NEW YORK.

LIST OF CONTRIBUTORS TO VOL. XXVI.

Agnew, Dr. C. R., New York.
Andrews, Dr. Joseph A., New York.
Averill, Dr., Campello, Mass.

Baird, Dr. W. T., Albany, Tex.
Baker, Dr. Henry B., Lansing, Mich.
Baker, Rev. Geo. S., New York.
Baldwin, Dr. Benjamin I., Montgomery, Ala.
Baldwin, Dr. D. A., Englewood, N. J.
Baruch, Dr. Simon, New York.
Binnie, Dr. John, Poynette, Wis.
Bodenhamer, Dr. William, New York.
Borcheim, Dr. I. E., Atlanta, Ga.
Bosworth, Dr. Franche H., New York.
Boyland, Dr. G. Halsted.
Bradner, Dr. Wm. B., Warwick, N. Y.
Brown, Dr. R. Wood, Kansas City, Mo.
Browning, Dr. Wm., Brooklyn, N. Y.
Buck, Dr. Albert H., New York.
Bundy, Dr. A. D., St. Ansgar, Va.
Burke, Dr. John, New York.

Canfield, Dr. H. A., Gillmore, Pa.
Campbell, Dr. S. E., South Bay City, Mich.
Carhart, Dr. J. W., Tampasas, Tex.
Carman, Dr. J. H., South Amboy, N. J.
Carpenter, Dr. Wesley M., New York.
Case, Dr. Meigs, New York.
Cauldwell, Dr. C. M., New York.
Chamberlain, Dr. Wm. M., New York.
Chapin, Dr. Henry Dwight, New York.
Cheesman, Dr. W. S., Auburn, N. Y.
Childs, Dr. S. B., Brooklyn, N. Y.
Christian, Dr. E. P., Wyandotte, Wis.
Cowan, Dr. George, Danville, Ky.
Crawcour, Dr. J. L., New Orleans, La.
Crothers, Dr. T. D., Hartford, Conn.
Crudeli, Dr. Conrad Tommasi, Rome, Italy.
Cuming, Dr. James, Belfast, Ireland.

Dana, Dr. Charles L., New York.
Dana, Dr. S. W., New York.
Davis, Dr. G. G., Trewsbury, N. Y.
Dickinson, Dr. D., U.S.N.
Doughty, Dr. W. H., Augusta, Ga.
Dumm, Dr. S. C., Columbus, O.
Dwight, Dr. Francis M., New York.

SOME REMARKS ON AFFECTIONS OF THE HEART.

BY J. MILNER FOTHERGILL, M.D. EDIN., HON. M.D., RUSH MED. COLL., ILL.

ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

I.

GROSS MUSCULAR CHANGES.

A PRELIMINARY word is desirable about these articles in order to prevent misconception. In a special treatise the matter must be thoroughly gone into from the bottom upward, as many readers will approach the subject in simple ignorance of it. But here it is assumed that the reader already possesses a fair text-book acquaintance with the heart and its various affections. With this explanation no mistake ought to occur.

The heart is liable to undergo certain changes of form known familiarly as hypertrophy and dilatation, and also atrophy in wasting disease. The latter needs no consideration here; it is but part, and not an important part, usually, of a general condition.

Dilatation, or elongation of the muscular fasciculi of the heart, is found in conditions where the chambers yield; conditions which vary considerably, viz., the heart-fibres yield under undue distention (which they are unequal to overcome), or are themselves weakened and so deprived of their normal vigor. Whether in a case of high arterial tension hypertrophy or dilatation takes place is a question of tissue-nutrition.

Hypertrophy is usually described as a muscular development to overcome some obstacle, as stenosis at the aortic orifice, or high arterial tension, as in the gouty heart. In both cases there is an obstruction offered to the ventricular systole, which the muscle meets by enlargement; a very intelligent action on the part of the heart, it must be admitted. But this view of some "intelligence" in the heart, by which its nutrition is modified to meet emergencies, is misleading. Is there some intelligence in the arm-muscles of the blacksmith, or in the muscles of the calf of the leg of a ballet-dancer? None that I ever heard of. What then is the explanation of these well-known facts? It is this: motor nerves are linked with trophic nerves; the message to the muscle to contract is accompanied by another message along the trophic nerve, which dilates its associated blood-vessels, and increases its blood supply. Consequently, increased functional activity in a muscle is followed by increased growth in it. This is spoken of as "hypertrophy," and whether it depends upon growth in existing fibrillæ or increase in the number of fibrillæ need not detain us here. But if the general nutrition is deficient, great action of a muscle leads not to hypertrophy, but to wasting, as seen in the well-known case of the top-sawyer so graphically described by T. King Chambers, in his famous "Clinical Lectures," in the chapter on "Atrophy of Muscles." His appetite suddenly failed, and his "shoulder muscles," those in most use by him, grew soft and weak from malnutrition. The reader who has this work at hand can profitably consult it at this point. He will see that great use of a muscle may lead to atrophy as well as to hypertrophy, according to the demand upon the muscle, and its nutritive supply. This is the great lesson which I desire the reader to take to heart, about hypertrophy and dilatation of the heart; and after this has been thoroughly realized it will not be difficult to put the subject of gross muscular changes in the heart-walls before him in a manner which will explain them without any hypothesis of "intelligence" in the heart.

The muscular structure of the heart-wall is ruled by its own ganglia in the heart itself. The primitive pulsatile sac has a nerve-centre with an afferent and an efferent nerve-fibril. By the afferent nerve-fibril the sense of distention is conveyed to the centre, whereupon an efferent message is despatched to the muscle to contract. Such a heart is a simple hollow muscle with its ruling nerve-centre. When the sac is full it contracts by means of the simple nerve-mechanism. The human heart is a very complex hollow muscle, with valves to economize power; while its primitive nerve-ganglia have connections with the rest of the nervous system by which the condition of diastole and systole—filling and emptying—is regulated according to the wants of the system. These are in the vagus inhibitory and also accelerator nerve-fibrils. The first come into action and to hold back the ventricular systole when the arterial system is full—the slow stroke of high arterial tension. The latter is found in action with a low blood-pressure—the fast, easily compressible pulse, which contrasts with the opposite condition.

Still, the great matter to bear in mind is the primitive hollow muscle with its nerve-centre and its afferent and efferent fibrils. The sense of distention is followed by a contractile action. When the hollow muscle is unwontedly distended a proportionately vigorous contraction follows. That is one matter. If the nutrition is well sustained the muscle waxes greater, in other words, becomes hypertrophied. That is another. It is the distention which leads to the muscular growth! That is the predominant idea to be borne lucidly in mind; and then why dilatation should occur in one case, while hypertrophy without perceptible enlargement of the ventricular chamber is seen in a second, and a blend of the two is encountered in a third case, becomes a matter readily and easily comprehended.

The heart-chambers are not of fixed size, they vary according to circumstances. This is readily seen by taking a spare, muscular subject, fixing the precise spot of the heart's apex-beat, and placing the tip of the finger thereupon. The heart can be felt at each systole quite distinctly. Then tell him to hold his breath. What is the result? As the right ventricle becomes more and more distended and intervenes as a "water-cushion" betwixt the heart's apex and the chest-wall, the apex-beat is lost. As soon as the right ventricle is relieved by the respirations being resumed, it recovers its normal size, and the apex-beat is quickly as palpable as before.

The heart, then, undergoes changes of form, and may be temporarily distended. This may be observed by causing a man to make an effort (as with a health-lift, for instance), and examining the heart while the effort is being made. Dilatation of the heart is *prolonged distention*. But at what point the condition of distention will be arrested by compensatory growth in the muscular wall depends upon the circumstances of each individual case.

In one case (a well-nourished person), the compensa-

tory growth will be set up so early that no perceptible dilatation occurs. In another, a condition of distinct dilatation is reached before hypertrophy's arresting hand can be brought to bear. In a third, there is dilatation without perceptible growth or thickening in the muscular walls. According to the amount of hypertrophy in proportion to the extent of the dilatation will be the amount of vigor in the heart. We speak of this muscular growth in the terms: 1, complete compensation; 2, incomplete compensation; and 3, no compensation. With the first the patient possesses great vigor, with the second some vigor, and with the third he, or rather she, is a crippled being. Why do I here say "rather she," not being a person in the habit of speaking of the "weaker" sex in a derogatory manner? Because dilatation of the heart is usual with women under circumstances where hypertrophy is rather the rule with men. In this sense of tissue-nutrition women are "weaker" than men. Take the gouty heart, for instance, with all its concomitants (to be discussed in a later article), with men we commonly find pure hypertrophy; with women there is, as a rule, dilatation, with more or less (and often less) hypertrophy.

The question of when, and at what point, the process of dilatation will be checked by compensating muscular growth, is mainly a matter of tissue-nutrition. There is another factor in action, however, and that is "time;" in other words, the urgency of the demand upon the heart-walls, the call for hypertrophy. If it come quickly, as, for instance, when an aortic valve cusp is torn down by a violent effort, some dilatation is inevitable, no matter what the nutritive powers of the individual. When the aortic valves are being soldered together slowly by a sclerosing valvulitis in an elderly, well-fed man, the demand is so gradual that the hypertrophied wall is found practically without any enlargement of the ventricular chamber. So the problem rests on the urgency of the demand versus the nutritive powers of the organism. Having grasped this main idea, the reader will experience no difficulty in recognizing the proportion of hypertrophy to that of the dilatation in any case which comes before him. Or in realizing the fact that the two are found together in every possible proportion, like the mixing of "old rye" and water. Or in understanding how, when the system is unequal to setting up complete compensatory hypertrophic growth of itself, it may be much aided by reducing the demand upon the heart (by rest in the recumbent posture), and by increasing the energy of the ventricular contractions (by remedial agents possessing such action) and improving the general nutrition. The malady and the means of remedying it, so read, are clear and unmistakable—to my mind at least.

When the heart-muscle has been temporarily weakened by acute disease, whether a general condition of pyrexia or the causal condition is one of myocarditis accompanying pericarditis or endocarditis, it is apt to become dilated; temporarily, certainly, in all cases. But whether the condition of dilatation will remain permanently or be removed, and at what rate it will be recovered from, will depend upon the amount of the demand upon the heart (*i.e.*, the extent to which effort must be made), and the amount of rest which can be given to it, as one matter, and the assimilative processes, aided by agents which increase the energy of the ventricular contractions, as the other.

By time, patience, and well-directed measures (supposing the patient to be able to command all), the system may be enabled to build up compensatory hypertrophy where, when unguided by knowledge and unaided by art, it is unequal to such effort. Such at least has been my personal experience.

It may now be well to proceed to discuss the circumstances under which such gross muscular changes are usually found, viz., obstruction to be overcome or an increase in the distending force to be resisted. Two matters which produce somewhat different results.

To commence with the aortic orifice. With stenosis or obstruction at this orifice the left ventricle is ordinarily found simply hypertrophied; sometimes, in women mainly, there is some dilatation. We can understand this readily when we remember that the lesion is slowly developed, allowing ample time for the building up of the compensating hyperplasia; and, to my mind still more, no great increase in the distending force. Here all that is required is some addition to the driving-power of the ventricle by which a normal bulk of blood may be driven in a normal time through a narrowed orifice. It is a slow process altogether, and the comparatively small hypertrophy is well maintained.

Far otherwise is the history of aortic regurgitation. Here the free edges of the valve-cusps are affected, with or without some dilatation of the aortic conus, and a regurgitant current of blood is driven backward into the left ventricle by the aortic recoil. It may be but a thin riband of blood, but it is sent into the chamber by a very different force to that which pours its current into the ventricle through the mitral orifice. The latter wells in rather, while the regurgitant current is driven in by the powerful recoil of the elastic arteries distended by the ventricular systole. Forcible distention of the muscular wall follows, and that brings with it, in its turn, hypertrophic growth, and we find a massive, powerful ventricle. So far so good. If the valvular mischief be the result of an acute valvulitis, and the mutilation of the valve be at once small and static, and the muscular development is in proportion to it, years may roll over the patient's head without perceptible change for the worse. Such, however, is not the usual history of a case of aortic regurgitation. Rather is it as follows: The enlarged ventricle is capable of throwing its contents into the arterial system with much energy, while in consequence of the enlargement of its chamber the amount of blood ejected at each systole is much above the normal amount; the distended elastic arteries recoil with an energy proportioned to the distending force, and a powerful current is driven backward into the ventricle. More distention of the muscular chamber leads to more hypertrophy, and then the huge *cor bovinum* of aortic regurgitation is found; but the limits of compensatory growth are at last reached. The huge muscle is insufficiently fed, and in time it undergoes degenerative change; and then the heart comes to a standstill in diastole, the decayed fibrillæ being unable to contract on full distention. From this we can comprehend the prognostic difference betwixt aortic stenosis and aortic insufficiency in regard to time. In the one there is only an obstacle to be overcome; in the other a new distending force is in action. In the one hypertrophy is moderate and well sustained; in the other it is huge and soon wears out.

Now let us consider the results of morbid action in the mitral valves. In stenosis the left ventricle is of normal size, or even below it, for the narrowed orifice obstructs the blood-flow into the chamber. But if the obstruction be slight, little change will be found in the left ventricle. Far otherwise is it in mitral regurgitation. Here the left ventricle has no obstruction to overcome; indeed there are two outlets for the blood now instead of one, and yet it is enlarged. How is that? Because the blood entering it on diastole is sent in with abnormal force from the gorged pulmonic circulation, plus the enlarged left auricle. There is no obstruction to the blood-flow offered at the mitral ostium, and the more powerful current dilates the left ventricle, with the consequence of increased muscular growth.

When the pulmonic circulation is impeded, whether by mitral disease or disease in the respiratory organs, the right ventricle enlarges. Incompletely emptied on systole, the swollen veins behind it pour in their contents, and distention follows, with enlargement of the muscular wall. As there is always an increase in the distending force in the case of the right ventricle, so there is always enlargement of the chamber, as well as a thickening of its muscular wall. But here again the proportions of

dilatation to those of hypertrophic growth vary according to the urgency of the demand and the powers of nutrition. The same measures are to be adopted here as were recommended in the case of the enlarged left ventricle, viz., rest, good food, and agents which increase the energy of the cardiac contractions.

Such, then, are the ordinary circumstances under which the walls of the heart undergo changes in form. The dilating process comes first, and, if the powers are equal to it, hypertrophic growth follows. At what stage of the dilating process the compensating growth begins to be efficient varies in each and every case; depending upon causes sketched out here in bold outline rather than in detail. To include the latter would be to extend this article beyond any limits that can be furnished by a journal. But that is no reason why the reader, having grasped effectively the outline here provided, should not work out the details in those cases which come immediately under his notice.

Rest, digitalis, and iron (with some strychnia), with good food, form a good line of treatment when nature cannot surmount her difficulty single-handed; but what must be done in each case depends upon its own requirements, of which the medical man in attendance can alone be the judge.

PRACTICAL OBSERVATIONS ON THE HUMAN EAR AND ITS DISEASES, WITH ILLUSTRATIVE CASES.

By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I.—The External Ear.

(Continued from Vol. xxv., p. 374.)

HÆMATOMA AURIS.

Synonym.—Othæmatoma; Perichondritis Auriculæ.

Hæmatoma auris is a disease of the cartilage and perichondrium of the auricle, with consequent formation of a cyst containing blood or varying portions of its constituents. These sanguineous cysts, as they are sometimes called, may be limited to a slight extravasation scarcely distinguishable from deep congestion, or they may consist in a tumor of greater or less dimensions. The tumor, although not always containing pure blood, has generally received the designation of blood-tumor. It may be produced either by severe contusion of the auricle, or it may, it is alleged, take its origin from idiopathic causes alone; most frequently, however, it seems to be due to violence, even where a predisposition to its occurrence exists. It is characterized by more or less inflammation of the cartilage and perichondrium of the ear, and by the sudden escape of sanguineous fluid between the cartilage and perichondrium, and, it is said, into the substance of the cartilage itself. The size of the tumor varies from that of a Lima bean to an egg; its formation is usually rapid, and the contents, at first fluid, show a marked tendency to become clotted, and quite often, unless incised, spontaneous rupture takes place.

In the milder attacks extravasation is so slight that it has been characterized as a serous œdema. The disease most frequently occurs in the insane, and produces such characteristic deformities that it is well known in insane institutions as the "insane ear," "shrivelled ear," and "asylum ear." The inflammation in this disease is generally adynamic in character; in certain cases, however, inflammation is liable to be more active. In a very considerable number of cases there is a strong tendency shown to spontaneous recovery.

HISTORY.

Traumatic othæmatoma.—The ancients were very familiar with this morbid condition of the auricle, since it was the necessary result of boxing-matches, which then constituted the favorite mode of combat. Among the Greeks and Romans pugilism was considered an essential part of education, as it increased the strength and developed boldness of character in their youth. Defence and assault with the fist or cestus were then extremely common, and combats for amusement even were the fashion of the day; the Grecian boxers, who were justly renowned, had for their titulary deity Pollux himself. The Æneid abounds in praise of these barbaric contests; thus in the combat between Eutellus and Æneas—

> "A storm of strokes, well meant, with fury flies,
> And errs about their temples, ears, and eyes—
> Nor always errs, for oft the gauntlet draws
> A sweeping stroke along the crackling jaws."

The implement employed by the classic slugger in these auricle-cracking feats was the cestus, a formidable gauntlet composed of thongs of several thicknesses of raw hide strongly fastened together and loaded with lead, iron, or brass, and bound to the arm by thongs. Four varieties of this crushing implement are known to have been in use, the least deadly being more dangerous even than the modern assassin's "brass knuckles," and capable of administering a fatal blow. These murderous weapons were known to Virgil as the "gloves of death." Paulus Ægenita refers to the aural injuries produced by this weapon as contusions of the ear, and Hippocrates described them as fractures of the auricle, adding that the injury was a common one in his day. "The combat with the cestus," he says, "was a favorite amusement of the ancients, and a blow about the ears was reckoned a master-stroke, sometimes being fatal." At a later date the amphotides, a helmet or headguard, was worn to protect the temporal bones, arteries, and ears. It was constructed with thongs and ligatures made of the hides of bulls, studded with knobs of iron, and thickly quilted inside to dull the concussion of blows. The pugilists and the pancratiastes, armed with the cestus, were in the habit of producing such disfigurement of the ears that it became a customary plastic ornament in antique sculpture, which thus affords abundant evidence of the results of these practices; for example, the heads of Hercules, Pollus, Hector, and other warriors have been represented with ears having this typical deformity of ancient contestants.[1]

The ancient custom of boxing has been continued by the Anglo-Saxon race, especially in Great Britain, where for a long time past it has been encouraged as a national amusement and has a literature of its own. During this period of time, however, the unprotected fist has been employed in combat, and the occurrence of the more serious aural injuries has in consequence diminished. Pugilism has now everywhere fallen into disrepute, and its votaries are principally confined to low resorts, where the boxers enter the lists with gloved fists and go through the forms of a "mill" for the amusement of the audience. Even here, however, we find that some vigorous blows about the head are demanded, and the ear is frequently struck, especially in "cross counter," in which the left ear suffers most. The frequent pounding of the left auricle in this manner often gives rise to othæmatoma. A very considerable number of persons are at present engaged in this occupation for a livelihood, and most of them have characteristically deformed auricles.

The tendency to violent contests has shown itself in other pastimes where the ear does not always escape injury; thus Farquharson[2] describes several cases of the disease under consideration, coming on suddenly, with oval swelling of the auricle, as a consequence of playing the game of foot-ball at Rugby, where there is much forcible butting with the head in "tight scrimmage."

"Idiopathic" othæmatoma.—The first description of othæmatoma, in which mental and other nervous dis-

[1] Vide Gudden: Hæmatic Swelling of the Ears of the Insane, Allg. Zeit. für Psychiatrie, Bd. xvii. Med. Critic. January, 1861. Ranking's Abst., vol i., p. 43, 1861.

[2] British Medical Journal, vol. ii., p. 59, 1873.

turbances play so important a part, was, I believe published fifty years ago by Dr. Frederick Bird,[1] then connected with the asylum at Sieburg. Bird gave a very good account of six cases coming under his observation, and drew attention to the intimate relations of the disease to insanity. The suggestions thrown out by Bird finally received the attention of other writers: M. Ferris, a Frenchman, gave the subject his attention in 1838, and ten years later (1848) the valuable essay on the subject by Franz Fischer[2] was written. The observations of alienists were naturally limited to the occurrence of the disease in insane persons; in 1852, however, an Englishman, Mr. S. Ozier Ward, drew attention to the liability of the mentally sane to the trouble.[3]

Numerous contributions have been made to the literature of the subject during the past thirty years. In 1858 an interesting paper was published by Stiff, "On Simple Sanguineous Cyst of the Ear in Lunatics,"[4] and in 1859 the distinguished labors of M. A. Foville were made known.[5]

It will be found on consulting the "Index Catalogue of the Library of the Surgeon-General's Office"[6] that, although incomplete as yet in respect to this subject, fifteen monographs and forty-six journal articles and other papers pertaining to othæmatoma were published between the years 1848 and 1879 by German, English, Italian, and American authors.

When it became known that mentally sound persons were obnoxious to the affection otologists soon gave the subject attention. Wilde[7] regarded it, however, as "a rare form of disease in man," and classified it among tumors of the auricle. The case cited by him, with clinical history and illustrative wood-cut, portrays a well-marked instance of the trouble in a mentally sane person.

Recognizing the similarity of his own case to the disease described by Bird as occurring in the insane, but having no experience in the latter affection himself, he made inquiries among a number of medical friends connected with lunatic asylums; from their statements, which, however, "varied as to its existence and cause," he considered that it was established that the disease affected a particular class of the community. Toynbee[8] afterward described the affection more fully than Wilde had done, and while regarding it as most generally confined to the insane, he himself had seen a case in a boxer, due to a blow upon the ear.

ETIOLOGY OF OTHÆMATOMA.

Of purely traumatic othæmatoma no mention need be made here, but in regard to the origin of the so-called idiopathic variety there has been much difference of opinion.[9] Bird was at a loss to account for its origin, never having traced it to outward injury, but in five of his six cases it is noted that there was active congestion of the head. Subsequently, Franz Fischer and others pursued the subject further and determined that the causes must ultimately be sought in pathological states of the nervous system.

One cannot witness the intense congestion of the ears, sometimes accompanying great cerebral excitement in the insane, without belief in the possibility of spontaneous extravasation of blood taking place beneath the perichondrium; and it is probable that where tissue changes, to be immediately referred to, have already taken place in the cartilage and perichondrium othæmatoma may sometimes thus occur. These nutritive changes in the auricle, believed to pave the way to extravasation, so to speak, will first demand our attention. They seem to be mainly brought about through the agency of the nervous system, although some authorities lay much stress on the influence of blood dyscrasias in producing changes in the blood-vessels of the part. The weight of evidence, however, leads to the conclusion that they most frequently depend on a morbid state of the brain, especially on congestion of the organ. Functional disturbance of the brain, or of the cerebro-spinal centre, giving rise to disorder of the cervical sympathetic, may, by reason of the dominance thus exercised on the vessel regulating nerves distributed to both intercranial ganglia and the auricle, set up hyperæmia in the former, and vascular changes in the latter.[1] When othæmatoma occurs in the course of general paralysis, it would seem that aural congestion took place in consequence of general degeneration of the sympathetic; and it has been suggested that in inflammation of the brain the aural disease becomes advantageous to the patient, since the hemorrhage is thus spent upon the posterior auriculars, coming from the middle meningeal.[2]

But while centric morbid conditions are justly regarded as of greatest importance, other impressions, propagated by morbid processes in other organs through the sympathetic system, are worthy of consideration; thus in the examination of insane subjects having this affection, the almost universal prevalence of nasal catarrhs, diseased teeth, and in the female of uterine disease, is notable, and it is well known that the irritation due to these influences is transmitted through the nerves, and may not only exasperate cerebral disease itself, but is liable to also affect the organ of hearing.

The predisponents believed to have an important relation to othæmatoma require consideration somewhat in detail:

Age.—Othæmatoma seldom occurs before adolescence; in regard to its appearance in the insane, it may be said that insanity is not obnoxious to youth, nor is degeneration of the cartilage liable to occur at this early age. Cases of contusion of the auricle are not frequently met with in children, but doubtlessly may occur at any age. Of the numerous cases reported as occurring in extreme youth, many of them were probably incorrectly diagnosed. Langenbeck reports a case occurring in a girl twelve years of age, who was said to be *wild*. Blau[3] describes a case observed in a gymnast, aged fifteen years, where there was no pschyco- nor neuropathic family history. The case had, it is said, no history of trauma, but it is significant that otorrhœa existed. Schwartze has seen a case in a child fourteen years of age, and Julius Erhard[4] speaks of cases arising in nurslings from rough handling or injury, causes from which the writer has never seen the affection arise. If the disease ever exists in young children, its occurrence seems to be quite exceptional. I have myself never seen such a case. The disease, moreover, has not been to my knowledge ever reported in extreme old age, which would seem to confirm the view that degeneration in structure alone is not a sufficient cause, but that its occurrence must be looked for in the active period between adolescence and the decline of life.

Insanity.—All forms of mental disease seem to be predisposing, but the conditions most favorable to othæmatoma are present in acute dementia where long-existing vaso-motor disturbances are followed by paroxysms of excitement.

[9] The writer's own experience in othæmatoma having been limited to cases occurring in the mentally sane, it was deemed advisable to observe the disease in the insane. Ample facilities for this were kindly afforded by Dr. T. M. Franklin, Medical Superintendent of the New York City Lunatic Asylum (for females), Blackwell's Island, and by Dr. A. E. MacDonald, Medical Superintendent of the New York City Asylum for the Insane (males), Ward's Island. To Assistant Superintendents Dent and Troutman, and other members of the staff of these institutions, the author's acknowledgments are hereby extended for courteous attention.

When the trouble occurs in the mentally sound, preceded by slight contusion, cerebral or other nervous disturbance has most likely existed, giving rise to trophic changes in the affected part. A tendency to insanity in such cases, however, is by no means always to be suspected.

Intemperance.—Intemperance in the use of alcoholic stimulants has a strong predisposing influence; I have repeatedly witnessed this in my own practice.

Cachexia.—A dyscrasia commonly attends cerebral disturbances in both insane and intemperate persons, and although othæmatoma by no means always appears in such subjects when the bodily health is most impaired, yet must we not entirely ignore a perversion of general nutrition, since this state may be in some degree predisposing. The scorbutic or rheumic diathesis may thus tend to impair the texture of the coats and laceration of the blood-vessels of the cartilage and perichondrium, when passive hemorrhages would more readily take place under undue excitement. Thus Dr. Wallace,[1] superintending physician of the Insane Asylum at New Ruppen, assumes a cachectic condition in conjunction with trauma as composing the etiological factors in othæmatoma.

Sex.—Writers are generally in accord respecting the greater frequency of othæmatoma in the male. Mr. Nicol,[2] who examined the ears of a considerable number of the inmates of the Sussex Asylum, found in 24 of them more or less deformity of the auricle, in several of them the disease being in progress. Of the 700 patients in the institution two women only were affected. Of the 249 asylum patients examined by Stiff—viz.: 124 men and 125 women—he found the cartilage of the ear more or less thickened in 17, probably the results of othæmatoma; of these 12 were males and 5 were females. In the six cases reported by Dr. Bird,[3] all of them were females.

Lennox Browne [4] examined 1,424 cases in the West Riding Asylum, 707 of whom were males, and 717 were females. He found that of the 32 patients affected 24 were males and 8 were females, making 3.39 per cent. of the males and 1.11 per cent. of the females affected—an average of 2.24 per cent. M. Foville, in alluding to this subject, says the affection occurs most frequently in males. Hun [5] reports 24 cases of the disease, 23 of them being males and one of them a female. The writer himself found in the statistics kindly furnished him by the Blackwell's and Ward's Island institutions for the insane, that among 1,309 females, 16 cases of othæmatoma were found, while in 1,269 males 14 cases were found, this inclusive of ears previously affected, as shown by deformity of the auricle, and those in progress at the time the examinations were made. This shows a percentage of 1.14 in females, and 1.10 in males. It will thus be seen that the greater number of cases occurred among females. In the opinion of some alienists female lunatics are more violent than males, and the observations of Dr. Bucke, of the Asylum at London, Canada, would seem to verify such a belief. In a recent report, in referring to the restraint required in an average population of 372 men and 394 women, he says that 25 men were restrained and secluded 4,079 hours, and 68 women 20,324 hours. The reporter offers no explanation for this, but states that on the whole females are more unmanageable than males.

Women are said to enjoy considerable immunity from the general paralysis of the insane, and consequently to escape the frequent paroxysms of excitement which characterize this phase of mental disease. On the other hand, women are subject to a monthly aggravation of symptoms during the menstrual period, since the mentally sane even are more irascible and nervous at this time.

The treatment of female lunatics, moreover, is more gentle than that of males, since their attendants are usually of their own sex, and less liable than male nurses to injure the ear in handling violent and idiotic patients. The ears of female lunatics are somewhat protected by their hair and head-dressings.

Traumatic agencies.—In the mentally sane the affection is most commonly met with among prize-fighters, gymnasts, persons given to violent sports, and among drunken and disorderly persons, where blows and falls are frequent.

As regards the insane there has existed much diversity among writers as to the cause. M. Bouteille, who does not absolutely reject the influence of predisposing causes, believes that othæmatoma never appears without violence to the auricle, and, in alluding to an epidemic of othæmatoma which occurred at Lyons in 1879, states that the trouble disappeared by simply changing attendants.[1] But it is believed that the ear is now less frequently injured by violence than formerly, since mechanical restraints are less in vogue, and an amelioration in the general management of the insane has gradually taken place. Not long ago it was not unusual for attendants to lead resisting patients by the ear, and otherwise maltreat the organ.

In some of the institutions for the insane where the writer has made inquiries concerning the prevalence of othæmatoma it would seem to be of infrequent occurrence; in one asylum a case had not been observed in "three or four years," and in respect to this matter in another institution the superintendent writes that the case books show that the "phenomenon has been regarded as a curious incident worthy of mention, but without sufficient importance in the history of the insane individual to merit description."

From a careful study of the subject the author has come to believe that othæmatoma is almost always due to violence inflicted upon the auricle. Asylum superintendents, however, have been on the whole, perhaps, rather disposed to undervalue the importance of mechanical causes, since it might be construed to imply undue restraint or rudeness in the management of their patients.

It is true that the trouble does not always supervene during paroxysms of violence, but it is difficult or impossible even to trace physical injury in all cases, or to show *per contra* that violent patients have not injured themselves. Othæmatoma is of quite common occurrence among those who give exhibitions of sparring and contuse the auricles by frequent blows with the gloved hand, and lunatics themselves injure their ears in like manner by self-inflicted blows. The extent to which this is carried by these unfortunate people, whose ears are, as a matter of fact, much less sensitive than normal, is much greater than would seem possible to any one unfamiliar with their habits. It is not uncommon for any one to strike with the fist upon a region of the body where a morbid process gives rise to slight pain, and I have seen sane persons pull and rub the auricle violently under certain conditions. The insane carry this much farther, especially when under excitement. One should not lose sight of the fact that the insane are liable to experience much discomfort in the ears from diseases of the organ, to many of which they are particularly subject, but mental disturbances from delusions and hallucinations are frequently so associated with tinnitus aurium and autophonia that the patient's attention is continually drawn to the ear. They have delusions respecting the presence of persons and things in the head, and concerning fancied attempts of "evil spirits" to gain admission thereto; they are in constant dread when awake because of the abusive and threatening language which they imagine to be spoken into the ears. Frequently the patient's voice be-

comes autophonous, when the ears and head seem "empty" or "cavernous;" it then becomes yet more difficult for the patient to not imagine or believe that abominable and dangerous occupants have taken possession of the disordered and void dormitory of the mind. Autophonia, which is an expression intended here to embrace the various forms of tinnitus as well as autophonous vocal and respiratory sounds, gives rise to hallucinations in mentally sane subjects even, especially in the aged and feeble.

Worthy of mention in this connection is the distressing itching and burning sometimes set up in the ear in neurotic subjects, relief from which is sought by constantly pulling, pounding, rubbing, and pinching the external parts. I have known sane persons to endeavor to get some relief from the torture of pruritis of the ear by treating the organ with much violence; a lady under my care at the present time often finds herself involuntarily scratching the auricle and temple on account of "creeping sensations" in the ear, and another patient, a clergyman, has the habit of thrusting a large pin deep down into the external auditory canal to scratch the parts; he also rubs the auricle at times until it becomes intensely injected.

Lunatics often thrust objects like wool, rags, etc., into the external auditory canal to get rid of disagreeable noises in the ears and head. The organ is frequently injured in this way; I have, for example, seen a case where much damage was inflicted by thrusting the rough end of a china doll's leg into the ear, and in another instance, a large abscess was produced on the inner surface of the auricle by rubbing and contusing it with a stone. In some instances, the insane strike the head against some object with great violence, the injuries thus produced leaving the auricles abraded and scratched; others thrust their fore-fingers into the ears and furiously shake and pull the organs—in one case seen a papillary growth was developed at the entrance of the external auditory canal in consequence, and the auricles were greatly enlarged.

It will thus be seen that insane persons very frequently have a fancy that the organ of hearing constitutes the portal of the mind, and we need not wonder, therefore, that it is so frequently assailed.

Among other numerous causes may also be enumerated the violent movements of certain insane persons when in bed; their pillows, frequently consisting of materials no softer than straw or husks, are liable to injure their ears, especially during their struggles under restraint. Again, when forcibly fed, while the head is held in the strong embrace of the nurse, the ears are liable to injury. Insane paralytics, if allowed to remain too long without change in position, may suffer from an interference in the process of nutrition on account of the undue pressure upon the ear, and rude handling of the head, as often practised by attendants, may likewise injure the auricle. Sloughing of the auricle from long-continued pressure in lying upon the organ in cases of fever not unfrequently occurs in the mentally sane.[1]

Othæmatoma has been described by writers on the ear as due to bites, burns, dentition, etc. Urbantschitz[2] reports the case of a woman where both ears were believed to be thus affected by a bite of some kind, and Kipp[3] reports the case of a child, considered to be thus affected, where both auricles were injured by a burn. Cases supposed to be due to dentition are related by Frank,[4] who says, "During dentition, this condition is often observed to occur, usually in scrofulous subjects." The writer, whose experience in this disease has been considerable, has never seen othæmatoma arise from any of these causes, and it seems probable that in some of them at least phlegmonous inflammation only may have been present.

In reviewing the causes of othæmatoma, it would seem that it has no special preference for either sex or for any one form of insanity, and that it may be produced in the mentally sane by contusion of the auricle. That it depends almost exclusively upon traumatic influences in all cases seems a warrantable deduction.

Occurrence.—The more frequent occurrence of othæmatoma in the left ear has been the subject of much speculation. Stiff[1] drew attention to this preference; he found that in 17 cases the left ear was affected in 6 cases, the right ear in 4, and both ears in 7. Of the 24 cases reported by Lennox Browne, the left ear was affected in 19, the right ear in 2, and both ears in 11; when both ears were affected the left was first attacked. The experience of some observers has been the reverse of the authorities above quoted, thus Hun[2] in his 24 cases found the right ear to be the seat of the trouble in 9 cases, the left in 5, both ears in 9, and in one the history was incomplete in this regard. In the cases where both ears were affected it is not stated which side was first attacked.

The greater frequency of occurrence in the left ear does not seem to hold good in the mentally sane with the exception of pugilists, who more frequently contuse the left auricle.

Various theories have been advanced in explanation of this peculiar manifestation. Thus it has been suggested that the near position of the left carotid artery to the heart affords a more direct blood supply to the left ear, and that, furthermore, the left pinna is oftenest affected because pulling or striking the organ is more liable to be done with the right hand, the left ear receiving the injury. The left ear, it is said, is also more liable to injury than the right in forcible feeding, since in holding the patient the arm of the nurse usually presses it with more or less violence against the head.[3]

An explanation of the greater frequency of left-sided othæmatoma, however, must be sought in some other direction, since the above apply to mechanical agencies only. It seems probable that some very intransient influence must exist to cause the trouble to appear so frequently on the left side, and could this be discovered, much light would doubtlessly be thrown not only on the etiology of othæmatoma, but also on other aural diseases. It has occurred to the writer that probably some vaso-motor influence might be found to lie at the bottom of the difficulty. It is a fact that unilateral sweating about the head is not an uncommon occurrence; and, moreover, in bilateral chronic catarrh the left ear is seemingly much more rapidly invaded than the right in a notable number of instances—a condition due, in all probability, to some vaso-motor disturbance whereby the nutritive process is interfered with much more on the left than on the right side. While this agency may be found to lie in some cerebral or cerebro-spinal condition, there exists a prominent irregularity in the distribution of the sympathetic nerves which it occurs to the writer might bring about such a result. Reference is had to the peculiar arrangement of the nerves extending upward from the cardiac plexus to the two sides of the head. According to anatomists there is to be found here an important irregularity. Thus, while an unvarying connection is maintained with the right side through the superior cervical ganglion, a comparatively imperfect and varying connection exists on the *left* side—the left superior cardiac nerve and the inferior cardiac branch of the pneumogastric only occasionally affording communication between the cardiac plexus and the left superior cervical ganglion.

Of course other but less direct communications exists which bring the cardiac plexus into relationship with the left ear, nevertheless the asymmetrical distribution above described might be the means of diminishing the vaso-motor dominance, in respect to the circulation in the left ear. Granting the correctness of the hypothesis, which, however, is by no means held to be indisputable,

[1] Williams' Treatise on the Ear, p. 108. London, 1840. [2] Lehrbuch, p. 89.
[3] Trans. A. O. Soc., 1867, p. 79. [4] Ohrenkrankheiten, p. 248.

[1] Loc. cit. [2] Loc. cit.
[3] The writer's attention was drawn to this latter explanation by Dr. Craig, Assistant Surgeon New York Asylum for the Insane.

the disparity in the vascularity of the two ears would finally produce distinguishing nutritive changes in the tissues of the parts—alterations especially well marked in the tympanic membranes in *otitis medio catarrhalis chronica*, where the membrane of the *left* tympanum will frequently be found to be quite parchment-like and lustreless, while the right membrane is yet in a fairly normal condition. It is thus difficult to see why nutritive changes may not affect the cartilage of the left ear more frequently than the right, and give rise to the greater frequency of othæmatoma on the left side.

Othæmatoma is frequently bilateral, very often developing equally on both sides. It may develop rapidly and disappear again as rapidly as it came. This bilateral invasion is suggestive of centric nervous origin.

Othæmatoma has been observed to occur during pregnancy. Gruber alludes to a case which came to his clinic in the fourth month of pregnancy.

YELLOW FEVER ON THE UNITED STATES STEAMSHIP PORTSMOUTH.[1]

By A. M. MOORE, M.D.,

SURGEON U. S. NAVY.

Endemic influence.—The only morbid influence of this nature that came under my observation was that of intermittent and remittent fevers at St. Thomas, W. I. These diseases prevail here every year, and all the year round. According to the statistical report of Dr. Magens, King's Physician, for the year 1883, there were 742 classified under this head, out of a total number of diseases of all kinds of 1,793—population estimated at 15,000. That they were light, however, is shown by the fact that there were only 4 deaths out of this number, the total number of deaths from all causes for this period being 415. The period of their greatest activity is that which covers the months of October, November, and December, the so-called rainy season. This term, it is obvious, is merely relative, as abundance of rain falls at all seasons; the mean annual amount being 46.8 inches. This "influence" was felt on board ship in the form of mild intermittents, two or three cases of which were under daily treatment during a twelve-days' sojournment of the ship at that place, but which promptly disappeared upon our departure. It is an interesting fact that the conditions under which these fevers exist here are not such as are generally conceded to be required for the production of *malarial* diseases. These conditions are best indicated by the names which have been applied to the whole class—"paludal," "swamp," and "marsh" fevers. Now, this island is a mass of trappean rock, devoid of vegetation except some species of cactus and a few small and hardy shrubs, and trees that can scarcely be dignified with the name. There is an entire absence of stagnant water, or even of fresh-water springs and streams, the rain which falls running rapidly down the mountain side into the sea. Again, malaria is rural, and not urban; it selects as its favorite habitation the fresh-water fens of the interior, and shuns salt water. But malarial fevers are *endemic* here, where the conditions are of a nature to lead one to expect to find, rather, yellow fever! Does not this circumstance suggest the possibility of interconvertibility under certain favorable influences? As a matter of fact, when an unacclimated person indiscreetly exposes himself to the miasmatic emanations here, he may possibly be stricken with *yellow fever*.

Report of three cases of yellow fever.—In order to complete and illustrate the remark under the head of "Endemic Influence," the anachronism is committed of reporting with the first quarter some cases of the above-named disease which occurred during the second. It is believed that this incongruity in time is justified by the increased value, if there be any, which will be thus obtained by placing in juxtaposition reports so closely related that one might be taken as a sequence of the other. Whatever may be the degree of relationship between malarial fevers and yellow fever, the fact is potent that, at a time when, according to the reiterated assurances of the American consul and king's physician, St. Thomas was, and had been for four years, entirely free from the last-mentioned disease, this disease was propagated from thence to persons on board this vessel. Such being the case, it becomes a serious question whether it is ever judicious, from a sanitary point of view, to send ships of this kind, with a crew composed largely of boys, who might become easily demoralized, to this port. In this connection it may be proper to state that every precaution was taken at this place to preserve the health of the ship's company short of absolute deprivation of liberty, which, indeed, was restricted to four hours during daylight. In view of the best information obtainable as to its good sanitary condition, this limited liberty was not considered injudicious. It is proper also to observe that at the military hospital visited there was no case that resembled in the remotest degree yellow fever. In addition to the three cases reported, there was another of a suspicious nature, which appeared on the 14th, and which was isolated with the rest, but as the subject of it, a marine, had not been ashore in St. Thomas, it is not included in the report.

CASE I.—The ship sailed from St. Thomas, bound for Hampton Roads, Va., early on the morning of April 5th, and, as before stated, the few cases of febriculæ disappeared very soon thereafter. About 3.30 P.M. of the 9th, four days out, Commander W. C. W——, who was last on shore for about four hours on the afternoon of the 4th, was taken sick—his illness being initiated by rigors, followed in about an hour by headache and fever. Temperature at 7 P.M., 103.5°; pulse, 90. Was put to bed, and 0.7 grm. quinia administered.

April 10th.—Temperature at 8 A.M., 101°; pulse, 90; at 7 P.M.: temperature, 102.2°; pulse, 72; vomited copiously in the morning a dark liquid, about the color of weak coffee, repeated in smaller quantity twice during the afternoon; vessels of conjunctivæ deeply injected; frontal headache and dizziness; pain in back, "as if it would break in two;" skin of forehead hot to the touch; face flushed; no epigastric pain or tenderness; marked hebetude; complete anorexia; specific gravity of urine 1032, scanty, dark colored, acid, with no trace of albumen.

April 11th.—Temperature at 8 A.M., 102.2°; pulse, 72; at 7 P.M.: temperature, 102.9°; pulse, 72; *urine albuminous;* vomiting of yellowish-white matter at intervals; is heavy, and sleeps much.

April 12th.—Temperature at 8 A.M., 101°; pulse, 55; at 7 P.M.: temperature, 100.9°; pulse, 47, weak and compressible; specific gravity of urine 1026, albuminous and scanty; continues to vomit at intervals small quantity of whitish matter; no recurrence of "black vomit" since second day.

April 13th.—Temperature at 8 A.M., 98.4°; pulse, 54; at 7 P.M.: temperature, 99.2°; pulse, 56; specific gravity of urine, 1024, highly albuminous; several copious and spontaneous dejections of dark green matter; heat of surface and headache less intense; ferrety appearance of eyes disappearing.

April 14th.—Temperature at 8 A.M., 99°; pulse, 56; at 7 P.M.: temperature, 99°; pulse, 58; urine albuminous, acid, specific gravity, 1026; headache and lumbar pain gone.

April 15th.—Temperature at 8 A.M., 98.5°; pulse, 60; at 7 P.M.: temperature, 99°; pulse, 60; urine highly albuminous, acid, specific gravity 1023, quantity increasing; great languor.

April 16th.—Temperature at 8 A.M., 99°; pulse, 58 and weak; at 7 P.M.: temperature, 98.5°; pulse, 50; albumen continues in undiminished quantity in urine; conjunctivæ jaundiced.

[1] From the report of sick for the first quarter, 1884

April 17th.—Temperature, normal; pulse, 54; urine albuminous; amount voided during last twenty-four hours 360 c.c. (12 oz.), being the largest daily quantity during the illness; specific gravity 1024; tinct. iodinii shows grass-green reaction of biliverdine. (This reagent was preferred to nitric acid, on account of the confusion of color produced by the latter on precipitated albumen. Pettenkoter's test failed to reveal the presence of the biliary substances proper, although great care was taken in its application—a specimen of urine being evaporated to dryness, the solid residue redissolved in alcohol, and a precipitate obtained by addition of ether, which was redissolved in distilled water, to which the test was applied. The failure to obtain any evidence of their presence may have been due, however, to lack of skill in manipulation.) Skin and conjunctivæ profusely jaundiced.

April 18th.—Temperature at 8 A.M., 97.4°; pulse, 47, with more volume; at 7 P.M.: temperature, 98°; pulse, 54; albumen decreasing in urine, specific gravity 1025; amount voided during twenty-four hours, 620 c.c.—marked increase.

April 19th.—Temperature at 8 A.M., 97°; pulse, 47; at 7 P.M.: temperature, 96.6°; pulse, 48; quantity of urine, 610 c.c.; specific gravity 1020, albumen decreasing in quantity; skin and eyes remain deeply jaundiced.

April 20th.—Temperature at 8 A.M., 97.2°; pulse, 54; at 7 P.M.: temperature, 98°; pulse, 48; amount of urine voided during past twenty-four hours, 720 c.c.; specific gravity 1024, *albumen entirely* disappeared.

April 24th.—Since last entry patient has improved greatly, and now sits up the greater part of the day; like Oliver Twist, he "wants more" to eat, and his diet is being cautiously increased daily. The yellow tint of skin and eyes, though still quite manifest, is daily passing away.

Case II.—On the morning of April 12th, Justin P. Q——, bugler, a native of France, aged about forty-two years, reported sick, with a temperature in axilla of 100.2°, violent headache with dizziness, face flushed, eyes bright and deeply congested, lower eyelids dark and swollen, as if by effusion of disintegrated blood into subcutaneous cellular tissue, heat of skin marked; tongue coated and is protruded with a tremulous motion; there is complete anorexia, though no pain or tenderness of epigastrium or back is apparent. States that he has been feverish, with headache, for last two days, which makes the commencement of his illness the 10th. Was ashore in St. Thomas from morning of March 29th till afternoon of next day, when he returned aboard "drunk and dirty."

April 13th.—Temperature, 101°; pulse, 90; urine straw-colored, scanty, acid, and free from albumen; headache and congestion of face and conjunctivæ continue; eyes closed by swelling of lids, which have a tendency to agglutination; facial aspect repulsive; odor of breath musty and highly offensive; anorexia continues, though no pain or irritability of stomach is complained of.

April 14th.—Temperature at 8 A.M., 101°; pulse, 96; at 7 P.M.: temperature, 101.8°; pulse, 98; urine acid, specific gravity 1028, no albumen; face and eyelids continue swollen and eyes congested; headache diminished; complete anorexia, but no nausea or gastric disturbance; gums spongy and bleeding.

April 15th.—Temperature at 8 A.M., 100°; pulse, 78; at 7 P.M.: temperature, 101.2°; pulse, 78; urine free from albumen; swelling of face and eyelids subsiding; headache giving way to soreness of scalp.

April 16th.—Temperature at 8 A.M., 99.4°; pulse, 74; at 7 P.M.: temperature, 100.4°; pulse, 78; urine free from albumen; facial aspect improving; head better.

April 17th.—Temperature at 8 A.M., 98.8°; pulse, 74; at 7 P.M.: temperature, 99.8°; pulse, 80; no albumen in urine; eyes much clearer; swelling of lids subsided.

April 18th.—Temperature, normal; pulse, 72; *urine albuminous*, straw-colored, acid; reports himself as feeling better.

April 19th.—Temperature, normal; pulse, 72; albumen in urine increasing in quantity; no pain or sense of discomfort in epigastrium or back; free alvine dejections of dark green matter—conjunctivæ jaundiced.

April 20th.—Temperature normal, urine albuminous, eyes jaundiced.

April 21st.—Temperature normal, urine continues albuminous; progressing favorably.

April 22d.—Temperature normal, albumen decreasing in quantity; skin and conjunctivæ clearing up.

April 23d.—Temperature normal; *albumen disappeared* from urine. From this time is dated the commencement of convalescence. There is no pain, and patient complains of nothing but unsatisfied hunger.

Case III.—George D. F——, third cabin boy, native of England, eighteen years and four months of age, reported on forenoon of April 13th, with following symptoms, viz.: intense frontal headache, giddiness, and mental confusion; eyes bright and conjunctivæ deeply congested; face flushed; racking pain in shoulder and knee joints; anorexia, but no nausea or epigastric pain or tenderness, and no lumbar pain; temperature, 99.2°; pulse, 100; states that he has suffered from headache and articular pains for two days, hence the accession of the disease is fixed at the 11th inst. Patient was ashore in St. Thomas from 1 to 8.30 P.M. on March 29th, the last two hours of which he spent sitting on the wharf, where, it is to be presumed, miasmatic emanations are the most virulent.

April 14th.—Temperature at 8 A.M., 100.2°; pulse, 96; at 7 P.M.: temperature, 102.8°; pulse, 100; tongue (dry and bare last night), moist; urine acid, specific gravity 1026, non-albuminous; articular pains better, otherwise much the same as yesterday.

April 15th.—Temperature at 8 A.M., 99°; pulse, 78; at 7 P.M.: temperature, 100.4°; head symptoms, as well as articular trouble, much better; no appearance of albumen.

April 16th.—Temperature, 99°; pulse, 76; head symptoms and articular pains entirely disappeared; anorexia persistent; eyes still congested; no albumen.

April 17th.—Temperature at 8 A.M., 99.8°; pulse, 80; at 7 P.M.: temperature, 98.5°; pulse, 78; conjunctivæ congested; urine acid, straw-colored, transparent, and non-albuminous; no pain or tenderness of epigastrium.

April 18th.—Temperature at 8 A.M., 99°; pulse, 78; at 7 P.M.: temperature, 100.2°; pulse, 78; character of urine unchanged; eyes remain congested; slight frontal headache; gums spongy and bleeding; lips dry and encrusted.

April 19th.—Temperature at 8 A.M., 98.6°; pulse, 76; at 7 P.M.: temperature, 98.4°; pulse, 60; no indication of albumen in urine; sponginess and bleeding of gums slightly improved.

April 20th.—Temperature at 8 A.M., 97.8°; pulse, 60; at 7 P.M.: temperature, 99°; pulse, 72; no albumen; injection of vessels of conjunctivæ fading; opened yesterday a large abscess over left parotid region.

April 21st.—Temperature at 8 A.M., 98°; pulse, 56; at 7 P.M.: temperature, 97.6°; pulse, 60; conjunctivæ less congested; *trace of albumen in urine.*

April 22d.—Temperature at 8 A.M., 97.2°; pulse, 54; at 7 P.M.: temperature, 98°; pulse, 48; urine more markedly albuminous; conjunctivæ jaundiced.

April 23d.—Temperature at 8 A. M., 97.4°; pulse, 48; at 7 P.M.: temperature, 98.2°; pulse, 60; albumen disappearing from urine, which is increasing in quantity; opened a small abscess in outer edge of nasal septum—left side. Doing well.

April 24th.—Temperature normal; urine abundant and albumen disappeared; patient is pronounced convalescent—the chief symptom being hunger.

The principles involved in the treatment of these cases consisted in rest of the stomach, and of measures adapted to relieve renal congestion and to increase the excretion and elimination of urine. In the case of Captain W——,

the type of the disease was different from that of Q—— and F——. In the former, gastric symptoms predominated and were quite serious for the first three or four days, while in the two latter the head symptoms were the most important and the cases approached more nearly the sthenic type. It will be observed that in these last cases the stomach was not at any time noticeably involved in the train of morbid symptoms, and it was only at a very late date that albumen made its appearance in the urine. In the case of Q——, the first indication of its presence was on the eighth day of the disease, and it had ceased to appear on the thirteenth; with F—— it was observed first on the tenth, and had entirely disappeared on the thirteenth day; while in Captain W——'s case it was found on the third day. and it was not until the eleventh that reagents failed to reveal its presence. Again, Captain W—— was profoundly jaundiced, while the other two were not at all markedly so.[1] Hence, while the principles of treatment were the same in all, these differences in type and symptoms made it necessary to vary the details. For example, the tincture of digitalis, which was used early with Q—— and F—— as a diuretic, could not be tolerated by Captain W—— until about the fifth day of the disease, on account of excessive gastric irritability. In all, revulsives were applied over the epigastrium and renal region, from the inception of the disease till the disappearance of albumen from the urine. The agents used for this purpose, and found effective, were sinapisms and tincture of iodine. Nothing whatever in the way of diet was permitted until the fifth day of the disease, when the blandest articles, as wine jelly, arrow-root, etc., were allowed, and the dietary cautiously varied and increased from that time. From about the eighth day, milk punch was, with appreciably good results, added to the other allowance. After albumen ceased to appear in urine, a tonic of quinia, iron, and acid. sulph. was substituted for the digitalis.[2] Captain W—— was, of course, treated in the cabin, access to which was prohibited to all except the surgeon and nurse (a man who had had the disease, detailed for that purpose). The other cases were isolated in the sick-bay, no one being allowed to enter there besides the surgeon, apothecary, and bay-man. This place was selected for the purpose because, first, there was no better; second, their isolation could be accomplished here with the least danger of attracting attention and arousing suspicion, a thing which it was obviously desirable to avoid. The atmosphere of the sick-bay was disinfected daily by diffusion of a saturated solution of carbolic acid by means of the steam atomizer.

The first case, Captain W——, occurred in latitude 25.08° N., with a temperature of 73° F.; the last, F——, in latitude 27.10° N., with a temperature of 76° F.

The favorable progress of these cases is largely due to the fact of their not appearing until the ship was well on the way to the north, and to getting soon into cooler weather. To the same cause the ship's company are undoubtedly indebted for their immunity from further attack. At noon of the 13th the ship had reached a temperature of 65° F., and from that time there was a steady decline till a temperature of about 42° was attained, about April 23d.

For the first few days after the first case announced itself, the situation, with two hundred and sixty-five human beings, mostly boys, enclosed in the narrow confines of a ship, in a tropical climate, and dependent upon the light and capricious winds of the "horse latitudes," was anything but reassuring. It was thought best by the surgeon and executive officer to conceal from every one the existence of the disease in the ship. But with these two the anxiety, while the ship lingered in the region of high temperature, was intense, lest each day might witness the accession of other cases to the sick list, and with the dire consequences of an epidemic on the *morale* of a crew of this kind staring them in the face. Then, as suspicion began to be aroused, with its resulting depression, the task of wearing a cheerful mien, with an apprehensive mind, was, indeed, a difficult one to successfully assume.[1]

[1] In all the cases there was noticed for the first few days a musty and peculiarly offensive odor of the breath, possibly due to carbonate of ammonium, from decomposition of retained urea.

[2] In the beginning the contents of the bowels were removed by an enema of soap, magnesiæ sulph., 30.00 grm., and water.

[1] The period of latency in the case of Captain W—— appears to have been about five days, though, as he was ashore two or three times prior to the 4th, it is uncertain. With Q—— and F—— it was eleven or twelve, and thirteen days, respectively.

Progress of Medical Science.

Laryngitis Hemorrhagica.—Dr. Stepanoff regards this affection as a distinct form of laryngeal inflammation, arising from the same causes as the catarrhal form, yet affecting females only. The primary symptoms are those of ordinary laryngitis, but after from three to fourteen days, hemorrhage occurs. It is sometimes excited by coughing, but may also come on without any noticeable cough. The amount of blood may vary from half an ounce to four ounces. There may be one or several attacks of hemorrhage, and after they have ceased, the symptoms of catarrhal laryngitis remain for a longer time than in the common form. Suffocative attacks occur but seldom. The laryngoscopic picture differs from that of the ordinary variety only in the presence of blood-clots. The intensity of the catarrhal inflammation stands in no relation to the amount of hemorrhage. Blood comes only from the true vocal cords and seems to occur by diapedesis, since it is readily controlled by a small injection of nitrate of silver.—*St. Petersburger Medicinische Wochenschrift*, April 26, 1884.

An Artificial Sponge.—Dr. Sampson Gamgee describes in *The Lancet* of May 3, 1884, a sponge devised by him, which combines absorbing power with elasticity, and is cheap enough to be burnt after use, thus rendering sponge infection impossible. It consists of an inner ball of absorbent cotton, surrounded with a wad of cocoanut fibres, around which again is a layer of absorbent cotton, the whole being enclosed in a gauze envelope. He found that a ball so made takes up readily from sixteen to eighteen times its own weight of blood or water, which when squeezed out still leaves the ball elastic and absorbent. The sponge may be rendered antiseptic by means of a very brittle ball or capsule, containing any antiseptic desired, and enclosed within the inner nucleus of cotton. By giving the sponge a preliminary squeeze, the capsule is broken and the antiseptic fluid set free.

A New Remedy for Phthisis.—Aluminium and its compounds are affirmed by Dr. Pick to constitute a most effective remedy against pulmonary tuberculosis, this opinion being based on experiments upon rabbits as well as on clinical observations. In one case, where infiltration of the apices of the lungs had occurred, removal of the lesion and all the morbid symptoms is said to have followed the administration of aluminium in the following form: Metallic aluminium, eight grammes; aluminium hydrate, five grammes; calcium carbonate, five grammes; gum tragacanth, in sufficient quantity; divided into sixty pills, one pill being taken three times a day.—*The Lancet*, May 3, 1884.

Diabetic Coma.—A case is related in *The Lancet* of a young woman who, except from an occasional headache, seemed to be in good health. She was found sitting in a chair, apparently in a profound sleep, from which, however, she could not be roused, except that she would raise her hand to her head when spoken to loudly. All attempts at resuscitation were in vain, the coma gradually deepened, and the girl died. There was no vomiting. At the autopsy no organic disease of any of the organs could be discovered, but the tissues gave forth a strong diabetic odor, and examination of the urine showed the presence of sugar in considerable quantity.

Carbolic Acid in Muscular Rheumatism.—Dr. Hurz recommends the employment of carbolic acid in intra-muscular injections for the relief of pain in muscular rheumatism. He uses a solution of 1–100 or 1–50. The injections are not painful, causing at the most but a slight burning sensation. The analgesic effect is manifested within fifteen or twenty minutes.—*L'Union Médicale du Canada*, May, 1884.

Mammary Atrophy.—Dr. J. W. Reynolds writes to *The Lancet* concerning a patient of his who is now in her fiftieth year. She ceased to menstruate about three or four years ago, and has borne six children. After weaning her first child, which she nursed for a few weeks only, she being twenty-one, her mammæ completely disappeared; not a vestige of gland could be felt, and there was no loose skin, but the chest and abdomen were as smooth as those of a child; but when she became pregnant the mammary glands enlarged to a very fair size, and there was an abundant supply of milk—too profuse, in fact, for it ran away continuously; and as it weakened her and did not nourish the child, she had to discontinue nursing. Then the glands would gradually disappear, the skin contract, and everything become smooth again. So with every pregnancy. Now, at fifty, her chest and abdomen are as smooth as any young girl's—no loose folds of skin or rugæ.

Cider as a Prophylactic of Stone in the Bladder.—Dr. Denis Dumont has examined the statistics of the Caen Hospital, and found that in fifty-nine years only four cases of stone in the bladder were admitted. In one the nucleus was a foreign body; and in two the patients drank wine, and not cider, which is the ordinary beverage in Normandy. An inquiry made in the neighboring departments of the Manche and Orne, showed that stone in the bladder was extremely rare where the use of cider was the rule. Meat being cheap and abundant in Normandy, the rarity of stone cannot be ascribed to the use of a food containing less nitrogenous substances than in other countries. The remarkable diuretic properties of cider, which the author has found useful in gravel, obesity, and some forms of gastritis, are considered to afford an explanation of this remarkable freedom from calculus.—*Birmingham Medical Review*, May, 1884.

The Prevention of Blindness in Infancy.—The following instructions, based upon the directions of the Society for the Prevention of Blindness, have been issued by the Manchester and Salford Sanitary Association, for the information of mothers and nurses (*Practitioner*, May, 1884): "One of the most frequent causes of blindness is the inflammation of the eyes of new-born babies. Yet this is a disease which can be entirely prevented by cleanliness, and always cured if taken in time. The essential precautions against the disease are: 1. Immediately after the birth of the baby, and before anything else is done, wipe the eyelids and all parts surrounding the eyes with a soft dry linen rag; soon afterward wash these parts with tepid water before any other part is touched. 2. Avoid exposing the baby to cold air; do not take it into the open air in cold weather; dress the infant warmly, and cover its head, because cold is also one of the causes of this eye disease. When the disease appears it is easily and at once recognized by the redness, swelling, and heat of the eyelids, and by the discharge of yellowish white matter from the eye. *Immediately* on the appearance of these signs *seek the advice of a medical man;* but in the meantime proceed at once to keep the eyes as clean as possible by very frequently cleansing away the discharge. *It is the discharge which does the mischief.* The cleansing of the eye is best done in this way: 1. Separate the eyelids with the finger and thumb, and wash out the matter by allowing a gentle stream of lukewarm water to run between them from a piece of rag or cotton-wool held two or three inches above the eyes. 2. Then move the eyelids up and down and from side to side in a gentle, rubbing way, to bring out the matter from below them; then wipe it or wash it off in the same manner. This cleansing will take three or four minutes, and it is to be repeated regularly *every half hour* at first, and later, if there is less discharge, every hour. 3. The saving of the sight depends entirely on the greatest care and attention to cleanliness. Small pieces of clean rag are better than a sponge, as each rag is to be used once only and then burnt immediately; sponges should never be used, except they are burnt after each washing. 4. A little *washed* lard should be smeared along the edges of the eyelids occasionally to prevent them from sticking. Special warning: Of all the mistaken practices which ignorance is apt to resort to, none is more ruinous than the use of poultices. Let them be dreaded and shunned as the destroyers of a newborn baby's sight. Tea-leaves and sugar of lead lotion are equally conducive to terrible mischief, stopping the way as they do to the only right and proper course to be taken."

Brittle Bones.—A case was recently reported to the Suffolk Medical Society, by Dr. Douglas Graham, of a patient who had sustained eighteen fractures during the first eighteen years of his life. They were distributed as follows: The right arm, broken nine times; left arm, twice; left leg, three times; right leg, twice; right and left clavicle, once each. The patient's father broke his bones fourteen times, and the father's cousin twenty-one times. The father's uncle was also a bone-breaker.—*Boston Medical and Surgical Journal*, May 15, 1884.

Increase in the Length of the Leg following Rheumatism.—Dr. Vinals reported to the Medico-Chirurgical Academy of Spain, the case of a young man in whom an increase of two inches in the length of the leg was observed to follow upon an attack of rheumatism in the knee. The reporter thought it due to increased activity excited in the still growing epiphyses by the articular inflammation. The inequality was not permanent, as the affected limb was in time overtaken in growth by its fellow.—*Revista de Medicina y Cirugía Prácticas*, April 22, 1884.

Spiræa Ulmaria in Enlarged Prostate.— According to Bauch, the queen of the meadows (*spiræa ulmaria*) is destined to occupy an important place in the therapeutics of diseases of the genito-urinary apparatus. He has administered an infusion of this plant to patients with enlarged prostate in whom urination or the passing of a catheter was very difficult, and within half an hour they urinated abundantly and freely. The queen of the meadows is diuretic, astringent, and antispasmodic, and exerts a special action on the sphincter of the bladder, spasm in which it relaxes.—*Revista de Medicina y Cirugía Prácticas*, April 22, 1884.

Treatment of Scrofulous Adenopathies.—Dr. García Andradas claims to have obtained excellent results in the treatment of sloughing scrofulous glands with the solution of the perchloride of iron (*El Dictamen*, April 30, 1884). He paints the surface of the caseous mass with the solution, and states that the slough is soon cast off, leaving a healthy granulating surface. This readily heals under an ointment of turpentine and vaseline, one part to fifteen. Of course the constitutional treatment is not to be neglected.

Physiological Albuminuria.—At a recent meeting of the Société de Médecine of Paris, M. Coignard reviewed and criticised the theories concerning albuminuria, and also the thesis on this subject written under the direction of Professor Bouchard. According to his personal observations, and those of a number of cases collected by Keller, physiological albuminuria does not exist. M. Coignard admitted the existence of transitory albuminuria, as also of transitory glycosuria, but denied that albumen is ever found in the urine of perfectly healthy individuals.—*British Medical Journal*, May 24, 1884.

THE CAUSE OF CHOLERA.—Mr. Vincent Richards has been conducting some experiments on pigs in regard to the cause of cholera, which have led him to very different conclusions from those of Koch (*Indian Medical Gazette*). He states that the choleraic discharges contain a virulent poison, which, however, disappears within a few hours, when decomposition has begun. He supposes the poison to be a chemical compound, and not a micro-organism, since he has found that it is destroyed by potassium permanganate. If the evacuations are rapidly desiccated without decomposition, the poison may retain its virulence for a considerable length of time and in this way be transported by fomites. He believes that the poison acts by paralyzing respiration.

THE SIGNIFICANCE OF THE PATELLAR TENDON REFLEX IN GENERAL PARESIS OF THE INSANE.—The following are the conclusions of a paper on this subject by Professor L. Bianchi in *Il Movimento* of May 15, 1884: 1. Exaggeration of the patellar tendon reflex may be a valuable diagnostic sign in the beginning of the disease, especially in those cases in which the *délire de grandesse* is not accompanied by disturbances of speech. 2. Although at the commencement of the disease it is as a rule exaggerated, it may in the further progress of the malady undergo certain changes. More often it diminishes or disappears, rarely becomes more exaggerated than before. 3. By itself, whether exaggerated or abolished, it does not indicate a determinate anatomical lesion of any special region of the cord occurring as a complication of general paresis. Therefore, instead of being considered as the expression of certain recent morbid processes, it should be studied in connection with the other symptoms of the disease, and not by itself or at any special period in the course of the malady.

MORPHINISM AND PREGNANCY.—Dr. Feré relates the case of a young woman addicted to the use of morphine in rather moderate quantity (about 3½ grains a day), who, when in the sixth month of pregnancy, endeavored to break off the habit. But any sudden diminution in the daily amount taken caused such severe uterine colic that the progress toward recovery was very slow. At the time of delivery she was taking about two grains per diem, and no attempt to reduce this quantity was made for a week. It was then sought to lengthen the intervals between the hypodermic injections, but the uterine pains returned and the lochial discharge ceased and did not reappear until the injections were resumed. At the end of a month the daily quantity of morphine had been reduced to a little more than one grain, and it was then withheld entirely. The patient suffered severely from uterine and intestinal colic and was unable to sleep the first night, but the following day all these unpleasant symptoms ceased, and she was definitely cured. The effect of the sudden abstinence upon the child, when birth removed him from the influence of the drug, was evident. He was a well-developed boy, though emaciated. He suffered from convulsive twitchings with continuous agitation and crying for sixty hours, during which time he did not sleep a minute. After that he recovered, slept well, and acted naturally. This fact would seem to indicate that, whatever may be said to the contrary, the fœtus is influenced by morphine even in relatively small doses, and that it may suffer from the sudden abstinence enforced by birth. This last consideration indicates the necessity of a gradual withdrawal of the drug in the case of opium-eaters who become pregnant. —*Il Movimento*, May 15, 1884.

DIAGNOSIS OF PLEURITIC EXUDATIONS BY THE TUNING-FORK.—The following are Dr. Federico's conclusions relative to the utility of the tuning-fork in the diagnosis of pleuritic effusions and exudations (*Gazzetta Medica di Roma*, May 1, 1884): 1. If the vibrating tuning-fork be applied to any part of a normal thorax, a full, distinct, and augmented sound results. 2. When made to vibrate while in contact with thoracic parietes within which there exists an effusion, and particularly if placed over that portion of the chest where the dulness on percussion is most marked, the tuning-fork emits a short, obscure, and muffled tone. 3. The sound is shorter and more muffled in proportion as the fluid is more abundant. 4. Although the author has, thus far, only experimented with serous effusions, he inclines to the belief that the sonorous vibrations of the instrument would be still more weakened and obscured if the effusion were rich in corpuscular elements. This theory derives support from the fact, experimentally demonstrated by the author, that the vibrations of a tuning-fork immersed in a watery fluid contained in a thin vessel are communicated to the receptacle, while the vibrations cease to be perceptible when the serous fluid is replaced by a purulent one. The author recommends the adoption of the following precautions in the application of the tuning-fork to its proposed diagnostic use: 1. The instrument should be placed in contact with corresponding parts of both the normal and diseased half of the thorax, for purposes of comparison. 2. An instrument with long branches facilitates the perception of slight variations in pitch and quality. 3. The vibrations imparted to the tuning-fork should be of moderate intensity lest they be transmitted to the stomach and colon and be thereby unduly augmented. 4. A certain amount of force should be employed in holding the instrument in contact with the chest-wall, as the vibrations are not well transmitted if this precaution be omitted.

ORIGIN OF MUSICAL DIASTOLIC AORTIC MURMURS.—Dr. Groedel, of Nanheim, reaches the following conclusions regarding diastolic aortic murmurs (*Berliner Klinische Wochenschrift*, April 21, 1884): The murmurs in question, often perceptible at considerable distance from the seat of their production, are caused by insufficiency of the aortic semilunar valves, if the valves are in such a condition that they may be put in regular and equal vibration, during the entire diastole, by the regurgitant blood current. The above condition obtains, first, when the first portion of the aortic arch is dilated and relative insufficiency of the valves is thus produced; and, secondly, in cases of genuine insufficiency, provided the valves be still capable of vibrating regularly and evenly.

A SUBSTITUTE FOR THE COLD BATH IN FEVERS.—Professor Preyer, of Jena, publishes in the *Berliner Klinische Wochenschrift*, May 5, 1884, an extract from a paper read by himself, at a meeting of the Jena Medical and Natural History Society, on a novel method of reducing animal temperature. The experiments upon which Professor Preyer's suggestions relative to the production of antipyresis are based were performed upon Guinea-pigs, but seem to show that the new method may be equally applicable to man. The means of refrigeration employed was the water spray. When the temperature of the water used was between 40° and 45° F., the rectal temperature of the animals, was reduced about 2° within from five to ten minutes. If, after the discontinuance of the spray, the minute particles of water entangled in the hair be allowed to slowly evaporate, the temperature continues gradually to diminish for several hours. If water at the temperature of 70° F. be employed the refrigeration is manifested within twenty minutes, but is not so pronounced. The rapidity and the degree of the antipyretic effect may thus be easily regulated by modifications in the temperature of the water used, and of the interval during which the spray is applied. The author states that the object of this communication is to incite to farther experimentation on animals as well as on the human subject.

ANTISEPTIC PROPERTIES OF BICHROMATE OF POTASSIUM.—Some experiments recently conducted in France show that urine, blood, milk, and other substances can be preserved from putrefaction during several months by the addition of one per cent. of their weight of this salt. —*Cincinnati Lancet and Clinic*, May 10, 1884.

Phlebitis Complicating Rheumatism.—M. Schmitt establishes two varieties of phlebitis accompanying acute articular rheumatism. One form of the disease manifests itself at the height of the rheumatic attack and augments the local pains and the temperature, while the joints become less tense and swollen. The phlebitis usually develops at the point of junction of the deep and superficial veins. Sometimes the veins remain permeable, the symptoms being confined to slight œdema, slight redness along the course of the vessels, and moderate pain. More frequently, however, this form of phlebitis produces obliteration of the veins, with more pronounced œdema, a cord-like induration, and, possibly, with petechiæ, ulcerations, and even pulmonary embolism. The second variety of phlebitis appears at the termination of the rheumatic attack, rapidly producing occlusion of the vessel, with more œdema, and with pain of considerable intensity. The phlebitis persists for several weeks, occasioning difficulty in walking and in moving the limbs. The femoral, popliteal, and saphenous veins are most frequently affected, but the radical and brachial are sometimes involved.—*Archives Médicales Belges*, April, 1884.

Concealment of the Cicatrix after Removal of Mammary Tumors.—M. D. Mollière describes an operation, devised by himself, for the purpose of hiding the cicatrix resulting from the ablation of an adenoma of the breast, located in the lower part of the gland. The tumor was about the size of an egg, and became regularly tumefied during the week preceding menstruation, resuming its former dimensions after the cessation of the monthly flow. The operation was performed as follows: A transverse incision having been made in the course of the submammary fold, the cellular tissue behind the mamma was separated from the glandular tissue, the encapsulated adenoma easily enucleated, and a drainage tube inserted. Union occurred by first intention, and the small linear cicatrix, being situated at the bottom of the submammary cutaneous fold, was completely hidden by the gland in its natural dependent position.—*Archives Médicales Belges*, April, 1884.

Nervous Diarrhœas.—Professor H. Nothnagel formulates the following conclusions regarding diarrhœas of purely neuropathic origin: Nervous diarrhœas, first so designated by Trousseau, are those which occur as the result of anxiety, fright, or various other intense physical impressions, and occasionally in hysteria, but which are unattended by intestinal inflammation. The diarrhœas in question may be chronic as well as acute. In certain individuals the above-mentioned etiological agencies merely occasion abnormal frequency of the alvine dejections. In other cases depressing mental impressions may cause a purely nervous diarrhœa to be engrafted upon a chronic enteritis, and to notably prolong the duration of the latter. The author cites cases illustrative of this disease, which, in his opinion, justify the establishment of two varieties of nervous diarrhœas. In one category belong cases in which the evacuations are of fluid consistency, in the other those attended by formed or hardened dejections. In the latter form the author believes that the nervous influence resulting in increased frequency of defecation is exerted upon the lowest portion of the large intestine in which fecal matter is already accumulated. In this case the only abnormal feature of the process is the occurrence of evacuations at unusually frequent intervals. A different nervous mechanism must be invoked to explain the occurrence of the fluid evacuations. The author assumes, in these cases, that either the entire bowel is affected by violent peristaltic movements, which mingle the fluid constituents of the discharges emanating from the small intestine with the solid fecal matter of the colon, or that an abundant transudation of serum, occurring in the large intestine itself, liquefies the solid matter previously accumulated therein. Professor Nothnagel inclines in favor of the latter theory, although unable to furnish convincing proofs of its accuracy. The exciting influences resulting in these two forms of diarrhœa must produce their effect through different nervous channels. In one case those nerves which, under stimulation, occasion increased peristalsis are incited to functional activity, in the other the vaso-motor and secretory nerves are chiefly instrumental in producing the diarrhœa.—*Allgemeine Medicinische Central-Zeitung*, May 14, 1884.

The Differential Diagnosis of Syphilitic Neuralgia.—Dr. Diffre (*Gazzetta Medica di Roma*, May 1, 1884) expresses the belief that the symptomatology of syphilitic neuralgia furnishes the most useful data for its differentiation from other forms of the disease. The clinical history and the results of treatment may also furnish considerable assistance. The author asserts that the pain of syphilitic neuralgia is intermittent, and that it manifests spontaneous exacerbations. If excited by mechanical means its intensity is diminished. The intensity of the spontaneous variety may vary from the lowest grades to such degrees of pain as might be produced by strong electric currents or the actual cautery. The pain extends along the course of the nerves, and is frequently limited to small areas. The neuralgic attacks are less frequent during the day, and even when observed at that time are of much less intensity than when occurring at night.

Reflex Paralysis.—A woman, thirty-four years of age, multipara, was admitted to hospital in the service of Dr. Gomez Torres, suffering from paralysis and atrophy of the upper extremities. Some months previous to her admission she had noticed that her hands were becoming thin and that she was gradually losing all power in them. The paralysis and atrophy increased in spite of persistent electrical and other treatment, until at this time she was unable to extend the hands at all, and the thenar eminences had entirely disappeared. Examination showed that she was suffering also from chronic parenchymatous metritis and extensive ulceration of the cervix. The diagnosis of reflex paralysis was made and was confirmed by the results of treatment, for the paralysis and atrophy rapidly disappeared as the local affection was relieved by appropriate measures.—*El Dictamen*, May 20, 1884.

Some Peculiar Forms of Aphasia.—Dr. Brown-Séquard, at a recent meeting of the Société de Biologie of Paris (*Gazette des Hôpitaux*, No. 48, 1884), recounted some curious facts concerning aphasia. The first case was that of an individual who had lost entirely the faculty of speech. He possessed but one word in his vocabulary with which he sought to express all his ideas. Yet he was able to sing in a loud voice, enunciating the words and rendering the music with artistic feeling. The second case was that of a physician of Cincinnati, who had become aphasic in consequence of softening of the brain. This patient had lost completely the use of language during his waking moments, but talked well in his dreams. The third instance was observed in an individual who was likewise suffering from complete aphasia in consequence of a cerebral lesion. His powers of speech were restored during times in which he was delirious. Dr. Richet related a fact somewhat resembling those just cited concerning an old woman who had been the servant of a priest. Just before she died she repeated very distinctly a number of Hebrew words which she had heard her master pronounce thirty-five years before.

Nitrite of Amyl in Ammoniacal Urine.—Professor Von Dittel observed at the Vienna Medical Society that he had for a long time past, in obstinate cases of ammoniacal urine, found this substance very useful. A solution is made of three drops in one hundred and fifty of water, and a tablespoonful of this is added to about a quart of water, with which the bladder is washed out. The unpleasant smell of the urine diminishes immediately, and is replaced by a pleasant ether odor.—*Dublin Journal of Medical Science*, June, 1884.

THE BUBBLING CARBONIC WATER BATHS OF NAUHEIM.—Drs. Augustus and Theodore Schott publish an article under the above title in the *Berliner Klinische Wochenschrift*, No. 19, 1884. The object of the paper is to give an unbiased statement regarding the chemical composition of the Nauheim carbonic acid waters, together with their nature, their *modus operandi*, and the indications for their use. Preceding the paper proper are certain general remarks on the history of carbonic acid water baths. The analysis of the waters, conducted under the supervision of Prof. Fresenius, shows that they contain an amount of carbonic acid gas fully equal to that of any other springs. The chief indication for the carbonic acid baths is found in the emaciation and anæmia attendant upon chronic diseases, and in moderate degrees of cardiac insufficiency resulting from constitutional diseases. High grades of anæmia and of cardiac weakness, however, contra-indicate the use of these baths, and are aggravated by them.

IODIDE OF POTASSIUM IN PNEUMONIA.—Regarding pneumonia as a general disease with local manifestations, Dr. Schwarz recommended the use of iodide of potassium in six-grain doses every two hours, at the same time applying an ice-bag to the chest over the seat of the pulmonary lesion. All his cases thus treated recovered, some of them within two days. Dr. Gualdi (*Gazzetta Medica di Roma*, May 15, 1884) has similarly treated a number of cases, and reports most excellent results. He formulates the following conclusions based upon his experience with this mode of treatment: 1. Schwarz's method of treating pneumonia gives good results. 2. These results are even better in the case of children than in that of adults. 3. The treatment should be instituted at the beginning of the disease, for when commenced at a later stage the cure is less rapid and satisfactory. 4. The action of the iodide is exerted upon the fever and the general disease, and not upon the local lesion. 5. The iodine and the potassium become separated within the organism and each of them exerts a special effect. 6. The action of the ice is upon the local condition. It is useful in the period of pulmonary congestion, but injurious in the stage of hepatization.

NITRITE OF AMYL IN OPIUM-POISONING.—Dr. W. L. Johnson reports in the *Texas Courier-Record* for May, 1884, a case of opium-poisoning treated by inhalations of nitrite of amyl. The patient when first seen, three hours after having taken two ounces of laudanum, was deeply narcotized, pulseless at the wrist, making six respirations to the minute, perspiring freely, with cold extremities, and cyanotic. Belladonna and other remedies having failed, twenty to thirty drops of nitrite of amyl were poured upon a handkerchief and applied to the patient's nostrils. After two inhalations of the drug the man looked up and asked what was the matter. From that time he continued to improve and made a good recovery.

CHILL AS AN ETIOLOGICAL FACTOR IN PNEUMONIA.—In an address delivered before the Birmingham Branch of the British Medical Association (*Birmingham Medical Review*, June, 1884) Dr. J. Burney Yeo expressed the belief that chill has a causal relation of some sort to many cases of pneumonia, but thought that its influence was often overrated. It is notorious, he says, that pneumonia often occurs during the prevalence of winds, especially the winds of spring; and not with winds from any particular quarter, for it is found to prevail with southwest winds as frequently as with east or northeast winds. Now, in this connection we have rather overlooked the fact that winds are carriers of dust as well as conveyers of cold (or rather, abstracters of heat); and that while, on the one hand, they carry away heat from the surface of the body, on the other hand they gather up dust of all kinds, and blow all manner of micro-organisms into our air-passages. It has been noticed again and again that all depressing agencies may predispose to pneumonia, such as exhaustion from physical fatigue and depressing emotions, and it may be that exposure to a cold wind acts both as a predisposing cause, by the depression of the normal resisting power it produces by rapid abstraction of heat, and also as an exciting cause, by means of the micro-organisms it blows into our air-passages.

A RARE TUMOR OF THE ORBIT.—At a recent meeting of the Academy of Medicine in Ireland (*Dublin Journal of Medical Science*, June, 1884) Mr. Story exhibited a tumor about the size of a small pea which he had removed from the orbit of a girl aged twenty. It had existed from earliest childhood, and had lately increased in size. The tumor lay beneath the lower lid toward the inner canthus, was freely movable in all directions, strong and hard to the touch, and was covered by slightly discolored skin. When the patient stooped, laughed, cried, or took violent exercise, this patch of bluish skin swelled. When the superjacent soft parts were divided the little tumor came out without further interference. On section it was found solid, and formed of a series of irregularly concentric layers, which microscopical examination showed to consist of fibrous tissue and calcified matter of an unknown origin, together with cellular conglomerations of an indefinite character. Nothing resembling either bone or cartilage existed in the tumor, its hardness being due to new calcification. Mr. Story considered the tumor to be a phlebolith, the history of the case and the pathological appearances agreeing with that view as to its nature.

TREATMENT OF CORYZA.—Surgeon-Major G. E. Dobson writes in *The Lancet* of May 31, 1884, describing a plan of treatment for coryza, which is certainly simple enough, and which he claims is very effective. About a drachm of camphor, coarsely powdered, or shredded with a knife, is placed in a small pitcher, which is then half filled with boiling water. The patient, having made a paper cone large enough to surround his face by its wide extremity and the mouth of the jug by its narrow end, proceeds to respire freely, at each inhalation drawing the steam into his nostrils, and at each exhalation forcing it up against the outer surfaces of his nose and adjoining parts of the face. A twofold action is produced: the camphorated steam acts internally in a specific manner upon the whole extent of the mucous surfaces, and externally produces profuse diaphoresis of the skin covering the nose and face, there acting as a derivative from the inflamed Schneiderian membrane. The pitcher should be wrapped in a woollen cloth to retain the heat in the water, or, better still, a tin vessel, under which a spirit-lamp is burning, may be used. The respirations should be continued for from ten to twenty minutes, and should be repeated three or four times in as many hours. The writer asserts that great relief is always felt even after the first application, and that three or four usually effect a cure.

A NEW FORM OF CUIRASS FOR POTT'S DISEASE IN YOUNG CHILDREN.—As a substitute for the plaster-of-Paris jacket, Professor H. C. Wyman (*Medical Age*) has devised a method of treatment which is briefly as follows: The child being placed in such position that the spine is extended to nearly the normal limit, a piece of Canton flannel, large enough to cover one-third of the circumference of the trunk, is laid on the back. A sheet of absorbent cotton having been placed over this, a cheese-cloth bandage six inches wide and several yards long, with the meshes carefully filled with plaster-of-Paris, is dipped in water and folded lengthwise over the whole. When rubbed smooth with the hand, so that it is perfectly adapted to the contour of the parts, a bandage is applied around the trunk, with figure-of-8 turns about the shoulders and pelvis, and the plaster allowed to set. The jacket thus constructed is in the form of a splint, and can be removed every night.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 5, 1884.

IMPROVEMENT IN INFANT DIET.

ANY step toward even the partial solution of the difficult problem of artificial feeding during infancy will be hailed with satisfaction by all physicians. The heavy mortality during the first year of life in those deprived of breast milk is, especially in cities, an important factor in the compilation of death-lists. Social science can roll up statistics, but is unable to suggest a remedy. Increasing importance is given to this question when we consider the large number, especially of American women, who cannot or will not nurse their children. In the majority of cases a wet-nurse cannot be procured, either from their scarcity or the attendant expense, and an artificial diet becomes imperative. A host of infant foods are offered as a perfect substitute for the mother's milk. All of these preparations, however, differ widely from the milk for which they are to be substituted. As a result, while some infant foods may produce a plumpness, they are all more or less colicky in their action. They are particularly not adapted to early infancy, when artificial food should not only be conformed to the baby's digestion, but should anticipate any future disturbances that are so apt to accompany the early months of life. Some of the preparations contain large quantities of unchanged starch that a young baby is unable to digest. Even the Liebig foods only claim to have transformed starch into glucose and thus removed one source of trouble; but the greatest cause of indigestion in cow's milk, the caseine, is not directly affected by them at all. It is true they are valuable by physically acting as attenuants of the caseine, as the arrowroot and cracker water formerly used, but they exert no chemical or physiological action upon this substance that is the source of so much of the indigestion during infancy.

In 1881 a council was held at Salzburg for the purpose of considering the subject of infant diet. Gerhardt, Henoch, Biedert, Soltmann, and other leading authorities were present. All agreed that advances in physiology only prove that mother's milk is quantitatively and qualitatively best suited to the development of the child. They likewise agreed that animal milk is the best substitute for breast milk. In discussing the subject of infant foods the chairman stated that it was unanimously agreed that these preparations can in no way be substituted for mother's milk, and, as exclusive food during the first year, are to be entirely rejected. The important question then to be considered is, how cow's milk can be best modified to resemble human milk.

Before discussing this question we will briefly notice the well-known points of difference between these two varieties of milk. Woman's milk is thin and watery, with a peculiar animal taste and a persistent alkaline reaction. Cow's milk, although containing more water and less solid ingredients, is more opaque, and very frequently has a slightly acid reaction. Human milk contains more milk sugar and fat, but a smaller percentage of albuminoids than cow's milk. A point of great importance is that the fraction of the total albuminoids coagulable by acids in cow's milk is much greater than that in human milk. The caseine of cow's milk does not coagulate in soft flakes as in human milk, but in harder and more indigestible masses. The usual method of preparing cow's milk is to add sufficient water to reduce the percentage of caseine to its relative amount in human milk. But in so doing the sugar of milk and fat, both already in smaller quantities in cow's milk than in woman's milk, have their amount still further reduced. A little loaf sugar is generally added to bring up the saccharine ingredients to their normal ratio. Hence to dilute the caseine properly the fat is diluted far too much. Now, if fat is removed from the milk, in addition to the loss of nutrition involved in its absence, the caseine coagulates in still harder masses. Even after the proper quantity of water has been added to cow's milk, with perhaps an attenuant, as a little starch or gum, the clot is only partially and incompletely diminished in size and density. The problem, then, is how to reduce the caseine and increase its digestibility, while at the same time the other important ingredients of the milk are maintained up to the standard of human milk.

Professor Pfeiffer, of Wiesbaden, in considering this subject brought out the valuable idea of peptonizing the milk. By this process the hard and objectionable caseine is physiologically changed into readily soluble peptone. The principal source of irritation in artificial feeding is thus removed. Cow's milk thus treated becomes thinner and bears a closer resemblance to human milk, while even if all the caseine is not digested, that which remains coagulates in loose flakes. Hence a digested, or easily digestible, caseine results from this process. As milk peptone has a bitter taste, it is as well not to completely transform the caseine. This artificial digestion of milk is effected by means of an extract of pancreas. Dr. William Roberts has tabulated four ferments as being present in the pancreatic juice—trypsin, curdling ferment, pancreatic diastase, and emulsive ferment. The trypsin changes proteids into peptones in neutral or alkaline media, and thus for practical purposes of artificial digestion, especially in reference to milk, has a great advantage over pepsine, which is only potent through the interaction of an acid. The caseine in the cow's milk is altered and partially or completely digested by the trypsin; hence any preparation of pancreas that does not contain this ferment in an active condition will be useless for peptonizing milk. Now that a reliable extract of pancreas can be obtained, this element of uncertainty is obviated. It may be asked whether the practical results of peptonizing the caseine of cow's milk are as beneficial in early infancy as the theory would indicate

As far as tried this question can be answered in the affirmative.

Professor J. Lewis Smith has the credit of instituting a series of trials at the Foundling Asylum which have thus far given satisfactory results, and he considers that peptonizing milk promises to mark an advance in infant diet. We have thus seen that cow's milk is the best substitute for human milk; that the former is apt to disagree with the infant on account of definite chemical, physical, and physiological differences that have been accurately ascertained, and that we now have the means largely to overcome. Let ordinary pure cow's milk be diluted with water, that has previously been boiled to destroy all germs, until its percentage of albuminoids has been reduced to the proper amount. Next add to it enough cream to make up the fat, and some sugar of milk. Then peptonize it with reliable extract of pancreas for the alteration of the caseine, and there is produced the best physiological imitation of mother's milk. The peculiar vital or maternal properties of human milk must always elude analysis, but to this limit we have well-nigh reached. Science, as always, stops before the mystery of vitality.

AN ENGLISH VIEW OF THE MORAL TENDENCY OF THE AMERICAN DOCTOR.

THE *Lancet*, in discussing the subject of the American Medical Association, takes the trouble to inform its readers that "there is a natural tendency in a very democratic country like America to demand that one man shall be considered as good as another, . . . and to obliterate the traditional morality which enjoins modesty of professional pretension and forbids the use of unworthy means for acquiring reputation and practice." Without stopping to demonstrate more clearly this relation between democracy and immoral pretensions, information is then given as to who a homœopath is, why he should not be met in consultation, and finally the American profession is told that they "will have a rough time of it if they do not stoutly maintain the principles" that are editorially indicated.

Thanks, awfully. But our esteemed contemporary, if correct in discovering our moral tendency, at least misapprehends the real issue before us, and leads its readers to infer that our moral degeneracy will be checked if we refuse to consult with irregulars. Now those who are referred to as "persons that ought to know better," appreciated long ago that there was some kind of a tendency in the profession not entirely praiseworthy, and saw that something was needed to check it, since existing codes did not. For one thing, a code was drawn up which forbade advertisements, and which tried to substitute individual liberty and responsibility for a restriction that had been long violated and dead. But, besides this, on all sides there has been an attempt to reform medical education, an attempt deprecated as "vulgar" in certain directions, but now warmly seconded by the mass of the profession.

The true issue to-day in America, as we would inform our didactic contemporary, is the educational, and coincidentally moral, elevation of the profession. For this we are striving, and we shall indeed "have a rough time of it" if this is neglected. A profession carefully educated, and composed of men who have had some moral training, will be certain to spurn quackery and fraud; and the question whether a man shall be at liberty to consult with whom he pleases becomes a pitiful side-issue.

A CRITICISM OF THE DEATH-RATE IN NEW YORK CITY.

A CERTAIN writer of the British [medical press seems anxious to do the people of this city a great statistical injustice. He has taken the pains to prove to the satisfaction of his unbiassed and cosmopolitan mind that the population of New York is now only a million instead of a million three hundred and fifty-five thousand, as our Board of Health fondly believes, and that consequently we are dying one per cent. faster than has been supposed, and is weekly reported. The true mortality rate, says this correspondent, is 34.01, or more, per 1,000, instead of 25.19, as officially given. If this charge be true, New York is one of the unhealthiest cities in the world, and our city Board of Health is shamelessly deceiving the people.

The reasons given by the critic referred to are as follows. He writes, speaking of the alleged great increase in the city's population:

"It is fair to assume that the residents in New York have increased since 1880, but not in the ratio indicated. That, however, I will pass by. The fact that the census return is inaccurate, and in excess of the truth, is more important. In the United States the census is not taken as it is in England. No day is fixed. On the last occasion it required fourteen months to get the returns in. Many of the persons whose names go on the census from their places of business in the city are non-residents, and they are put on record again in Brooklyn, or New Jersey, or Staten Island, or wherever they happen to live. I and my family were among the large number who were taken twice at the last census. Twenty-four per cent. of the members of the Stock Exchange are non-resident. In the Cotton Exchange the numbers are about the same. In the Produce Exchange sixty per cent. of the members live out of town. The resident population of New York does not exceed 1,000,000. I doubt if it is so much."

He then proceeds to make another estimate based upon the registration of voters. The total number registered in 1883 was, he states, 182,531; multiplying this by five, we get only 912,655 as the total population, which is nearly half a million less than the last estimate (1,355,000), upon which our sanitary authorities base their returns.

We do not propose to attempt to prove that New York is a remarkably healthy city, and has over a million of inhabitants. We leave this to our sanitary authorities. But we would call attention to certain sources of error in our critic's mode of calculating. The census is taken in June, when the swarms of tramps and vagabonds which infest the city and swell its mortality, as well as thousands of respectable families have left town for the summer. Any estimate of population based upon the number of registered voters is utterly untrustworthy, for reasons which American citizens very well know, and which need not be entered upon here.

New York City receives a vast influx of transients, including immigrants, of whom the sick remain while the well pass on. Consequently the death-rate in its institutions is very large, amounting generally to one-fifth of the whole.

The causes of the high and hypothetical death-rate estimated as above are asserted to be bad air, bad water, bad food, bad drainage, imperfect sanitary measures, and crowded tenement-houses, which we are told exceed in filth even the London slums. All of which is news that ought to be gratefully received by our sanitary authorities, whose eyes have heretofore been blinded by a mistaken patriotism and a desire to make a good showing to the people.

Finally, says *The Lancet* correspondent, the great mortality is due "last, but not least, to the inefficiency of medical help. I say it advisedly, but emphatically, after several years of close observation in the United States, that the rate of mortality generally, as well as in the city, would be very materially lowered if the standard of medical education were adequately raised."

To this we would simply say that he is probably in a measure right; yet the late President of the American Medical Association has asserted it to be in bad taste, if not absolutely vulgar, to refer to the fact that American medical education is not just what it ought to be.

NOTES ON SUMMER VACATIONS.

We had declined several excellent articles upon the timely subject of doctors and summer vacations. We have, however, recently received from various sources several such pertinent letters regarding the relations of summering physicians to patients and public that it was deemed wise to present them at once to our readers.

The first is from the father of a family who is boarding at the seaside:

Mr. Editor, Dear Sir: I have sent my family, consisting of my wife and six children, to spend the summer at —— ——. I am paying ten dollars a week apiece, a rate which is likely to consume most of the money I have laid aside for the summer. When I am at home my physician charges me $2 a visit, but last year at the sea-shore I was charged $5, which included social calls and several bouquets for my wife. Will you kindly use your influence to persuade the summer-seaside physician to be more reasonable in his charges and leave me a little money with which to move back to town in the fall? Very truly yours, Paterfamilias.

Another is from a lady in the city:

Dear Mr. Editor: I expect to be confined about the middle of August. My family physician is obliged to go to Europe this summer to study, and all his acquaintances will be in the Adirondacks at that time for their health. I know of no physicians who will be in town then, except a few homœopaths and the members of the Assistant Sanitary Corps. What am I to do?

Sincerely yours, —— ——.

A third is from a local physician at a fashionable health resort in the interior:

Dear Doctor: I have a very fair practice in this town during the year, but I have until lately looked forward to the summer months as being especially useful and lucrative. For several years past, however, Dr. A——, of New York, has been up here and taken all the gynecology, Dr. B—— has absorbed the ear, eye, and throat cases, and this year I learn that Dr. C—— is expecting to be here to attend to obstetrical cases and nervous exhaustion. It seems to me that this is hardly fair, as I believe that I have been quite successful with visiting invalids before and only charged one-third as much. But I am not, unfortunately, a New York or a Philadelphia professor. Can you not secure a little justice to us rural doctors?

Yours very truly, —— ——, M.D.

Finally we have received the following curious letter from the proprietor of a large seaside hotel:

Dear Sir: I wish to secure a physician to reside at my hotel during the summer, and I beg for your advice in getting one who will be a little more satisfactory to my guests in certain respects than those who have heretofore been established with me. The medical gentlemen previously here have all been of excellent manners and fine professional attainments, but their charges have been enormous, even compared with my own. Dr. X——, who was here last year, charged Mrs. L—— $5 for brushing by her on the piazza, and $10 for putting her baby in the omnibus. As he danced several times with her daughter she could not refuse to pay. But such things are making my hotel unpopular with invalids.

Can you suggest some competent man who charges moderately?

Very respectfully yours, —— ——.

The Cholera in Europe.—The progress of cholera at Toulon may be best seen by the following table, showing the number of deaths since the disease was first noticed, June 14th: June 14th, death 1; June 19th, death 1; June 20th, deaths 2; June 21st, deaths 3; June 22d, deaths 13; June 23d, deaths 5; June 24th, deaths 12; June 25th, deaths 9; June 26th, deaths 10; number of cases, 62; June 27th, deaths 4; June 28th, deaths 6. On June 29th, two cases of apparent cholera were reported at Marseilles; on the next day five deaths from the disease were reported. A case was also reported at Saluzzo, Italy, on the 30th. The opinion so far continues to be that the disease is undoubtedly Asiatic cholera. The form of the disease was at first reported to be mild. A great deal of alarm has been excited throughout Europe. Extraordinary, and in some cases foolish, precautions are being taken to prevent the spread of the disease. The roads and passes in France leading from Toulon have, it is said, been narrowly guarded. Spain has established a military cordon along its frontier. Quarantine against vessels from French Mediterranean ports has been established at Madrid, Trieste, Gibraltar, and other ports. A medical inspection of railway passengers from Southern France has been established in Italy, Austro-Hungary, and other places. Professor Virchow takes the opportunity to blame the French Government for careless sanitary measures. Toulon appears certainly to have been a very dirty place, but Marseilles was reported clean and healthful at the time the cholera appeared.

News of the Week.

St. John's Guild.—This excellent organization, that has been in existence since 1866, hopes to continue its excursions this summer for the benefit of sick children. Last summer the floating hospital made 32 regular excursions and 12 extra excursions, carrying 29,189 children and mothers or guardians. The sea-side nursery also did good work in keeping children for several days or a week in the country. Many children with diarrhœal diseases had their lives saved in this manner. Money is needed to carry on this work, that commends itself to all charitable persons.

The State Board of Health has discharged its corps of experts engaged to examine into adulterations in food and drugs, owing to lack of funds.

New Asylum for the Chronic Pauper Insane.—The Commissioners of Charities and Correction have bought a tract of land of 1,067 acres on Long Island, between West Deer Park and Farmingdale. They intend to erect upon it buildings for the chronic incurable pauper insane.

The Sundry Civil Appropriation Bill, as reported to and passed by the House, provides for a repeal of the law creating the National Board of Health.

The Medical Register of New York, New Jersey, and Connecticut for 1884–85, which has just been published, contains the names of 6,247 physicians. Of these the New York State list contains 2,686 against 2,684 last year, and the New York City list 1,789 names against 1,661 in the previous year. The number registered in the State at large, therefore, has decreased; that in the city increased.

The Worthy and Suffering Poor of this city have only twenty-five dispensaries out of which to select their medical and surgical attendants. We chronicle with pleasure, therefore, the organization of the Good Samaritan Dispensary, which is "to give medical aid to the indigent," thereby supplying a long-felt want.

The Summer Sanitary Corps of physicians has been appointed, and report for duty July 6th.

The Garfield Memorial Hospital, Washington, D. C., opened on June 18th for the reception of patients.

The Cattle Disease in Kansas and Illinois.—Professor James Law has made an elaborate report upon the disease which appeared last winter and spring among the cattle in Kansas and Illinois. He concludes that the animals suffered from dry gangrene, the result of eating ergoted hay and corn. Professor Law's report contains a valuable review of the subject of ergotism in cattle.

The Vote to Admit Women into the Massachusetts State Medical Society has led the *Boston Medical and Surgical Journal* into the expression of certain atrabilious Anglicisms. It refers to the practice of medicine by women as a "foolish fad." Many will believe this to hit the case exactly; but they must admit also that something has to be conceded to abstract justice, the unmarried legion, and social peace.

Other Discoverers of the Cholera Bacillus.—It is reported that Dr. Carter, Acting Principal of the Grant Medical College at Bombay, has found the cholera bacilli in the perfectly fresh dejecta of cholera patients. Dr. Weir, of Bombay, has found the same bacilli in the well-water drank by cholera patients.

Professor William Pepper has succeeded Professor Stillé at the University of Pennsylvania, instead of at the Jefferson Medical College as stated.

Dr. Yeng Tis Hing.—On the recommendation of Dr. Woolsey Johnson, Yeng Tis Hing, a Chinaman, was recently registered as a practising physician at the Board of Health. It remains to be seen whether he is Old Code or New Code.

Bequests to Medical Charities and to Harvard Medical College.—The late Samuel W. Swett left in his will a bequest of $50,000 for the Massachusetts General Hospital, to establish a convalescent department; $10,000 to the Children's Hospital of Boston; $10,000 to the New England Hospital for Women and Children; $20,000 for the Medical Department of Harvard College.

Deaths in a Foundling Asylum.—Somewhat sensational accounts are given in the daily papers of a foundling home which was opened last January, at Hammonton, N. J., under the charge of a Miss Niverson. Twenty-three infants from Philadelphia, New York, and elsewhere were brought to the institution. It is stated that all but two of these have died, not having received meanwhile proper medical attendance. The New Jersey Health Board will investigate the matter. The deaths occurred chiefly from measles.

Medical Instruction in Japan.—A meeting under the auspices of a committee of gentlemen consisting of Bishop Stevens, Drs. D. Hayes Agnew, William Pepper, and others, was held in Philadelphia, June 12th, for the purpose of inaugurating a movement looking to the establishment in Japan of a medical college, hospital, and training school for nurses. The plan is largely the outcome of the efforts of Dr. John C. Berry, formerly of Maine, but for the past twelve years a medical missionary in Japan. Dr. Berry explained the project at length. He estimated that to establish a permanent endowment of one professorship $45,000 would be required. Resolutions were adopted indorsing the project, and in furtherance of the plan as contemplated a committee was appointed to confer with similar committees in other cities of this country.

The International Medical Congress.—We have received the programme of the eighth session of the International Medical Congress to be held in Copenhagen, August 8 to 16, 1884. All medical men legally qualified to practise in their respective countries are entitled to membership on paying the subscription fee of twenty crowns (Danish), equivalent to $5.50 in our money. Each member will receive a copy of the "Transactions" when published. The work of the Congress is divided into fourteen sections, meetings of which will be held daily from 10 to 12 and 1 to 3. The general meetings will be held each day from 4 to 5.30, and in addition some address of a more popular character will be delivered in the evening from 8 to 9.30. The official lan-

guages of the Congress are English, French, and German, but communications which cannot be made in all three languages will be given in French. The number of papers and communications prepared or announced for delivery in the general and sectional meetings is over two hundred and fifty. Members of the Congress, through the courtesy of the Danish Government and the United Steam Navigation Co., of Copenhagen, will be furnished with return tickets gratis from Copenhagen to the frontiers of Denmark (Fredericia or Kiel). A bureau of information for the benefit of the members will be established at the station of the Korsör-Copenhagen Railway. All letters of inquiry in regard to lodgings, etc., should be sent before the end of July to Professor C. Lange, Secretary-General, 22 Kronprinsessegade, Copenhagen, K., Denmark.

The late Dr. J. G. Adams.—At a stated meeting of the Council of the New York Academy of Medicine, held June 24, 1884, the following preamble and resolutions were unanimously adopted :

Whereas, The Council of the New York Academy of Medicine has heard with profound regret of the recent death of their associate, Dr. John G. Adams, an original Fellow, and, at the time of his decease, Corresponding Secretary of the Academy ;

Resolved, That the Council desire to put on record their warm appreciation of his fidelity to his convictions, his genial friendship, his ripe culture, his courtesy, his liberal, earnest, and persistent interest in the Academy, and of his gentlemanly and Christian character.

Resolved, That a copy of the above preamble and resolution be entered on the minutes, be published in the medical journals of the city, and sent to his relatives.

G. M. Smith, M.D.,
H. T. Hanks, M.D.,
Committee.

The Late Dr. William Hustace Hubbard.—*Whereas*, Dr. William Hustace Hubbard, a late member of the house-staff of Bellevue Hospital, has been removed by death, in the beginning of his professional career ; therefore,

Resolved, That this board now expresses its appreciation of his manifest sterling qualities as a man, and of his faithfulness and earnestness in his professional work ; also,

Resolved, That in the death of Dr. Hubbard we have lost a worthy assistant, and the profession at large a most promising, able, and upright member.

Resolved, That we tender our heartfelt sympathies to his respected father Dr. Samuel T. Hubbard.

W. Gill Wylie, M.D.,
A. Brayton Ball, M.D.,
George L. Peabody, M.D.
Committee.

Another Microbe is Born.—It was discovered and cultivated by M. Duclaux. It is that of the disease known as the *bouton de Biskra*. A patient from Tunis suffering from this affection was admitted to the Hospital St. Louis, where the pathology of his condition was investigated.

Bergh and Pasteur.—Mr. Henry Bergh, of this city, has sent some of his ravings, in the form of a letter, to the President of the Paris Society for the Prevention of Cruelty to Animals. We publish some of the gems from this letter. Mr. Bergh writes : "But, revolting as are these canine massacres, they fall far short of the barbarities of M. Pasteur, both in their atrocity and in the fatal consequences to the physical as well as moral well-being of the French nation. In the outraged name of science this merciless empiric is poisoning the flocks and herds of France, after the fashion of his predecessor, the notorious Jenner, of England, who nearly a century ago commenced inoculating his countrymen with a noxious mucus taken from diseased animals, under the pretence of preventing and curing small-pox. That the human race, through the unfortunate existence of Jenner, has been hopelessly deteriorated ; that scrofula, cancer, and consumption, along with their hideous long trains of chronic diseases, is the fearful legacy of that man's presence on earth, some of the most learned and conscientious scientists have declared to be their belief. A French Jenner now crawls to the earth's surface and begins the fiend-like and disgusting work of polluting the bodies and flesh of the lower animals ! Moreover, it is proposed in the Chamber of Deputies to reward this man's detestable crime by voting him a pension also."

Death from Chloroform given in Child-birth.—A death under chloroform occurred recently at St. Bartholomew's Hospital, attended by circumstances of an unusual character. The patient was a woman seven and a half months pregnant, who had been admitted into hospital on account of placenta prævia. On the day preceding the fatality, chloroform had been taken by the woman without any symptoms indicative of danger ; but soon after the second administration was commenced, respiration and pulse became suspended, and death was unmistakable.

Obituary.

JOEL FOSTER, M.D.,

NEW YORK.

Dr. Joel Foster, one of the oldest practising physicians in this city, died on June 29th. He had been ill for about a month and a half, but was not confined to his bed until a week prior to his death. Then he sank gradually, and expired at an early hour on the above-mentioned date. He was born in Barnard, Vt., March 10, 1802. His ancestors were among the original settlers of Vermont and figured in the French war, and he was also a distant relative of General Stark, of Revolutionary fame. He first studied medicine in Woodstock, Vt., under Dr. Gallop, and afterward removed to Philadelphia, where he resumed his studies in Jefferson College. Here he graduated with the highest honors.

After securing his diploma he married and began his work as a physician in Schoharie, N. Y. In 1855 he came to this city, and since that time has been busily engaged in his practice. When the President called for volunteer physicians, after the second battle of Bull Run, Dr. Foster secured thirty-seven doctors from the Academy of Medicine in this city and started for the field. He did good service in administering to the wants of the wounded, and gained honorable mention for his work in this respect. Dr. Foster was the oldest life member of the State Medical Society, and was one of the founders of the Academy of Medicine in this city. He was also prominently identified with the Infant Asylum. He was a prominent and active abolitionist and was a friend of William H. Seward.

Reviews and Notices.

Diagnosis and Treatment of Diseases of the Heart. By Constantine Paul, Member of the Academy of Medicine, Physician to the Lariboisière Hospital. New York: William Wood & Co. 1884.

Dr. Paul's treatise on cardiac affections, which is the March number of Wood's Library, is a systematic and practical exposition of this interesting and important class of affections. In all that relates to etiology, symptomatology, and diagnosis, we know of no better work. In the chapter on treatment we miss that detailed account of what is at present known with regard to the therapeutics of the various stages of cardiac diseases that one might expect in a special work of this kind. In spite of this drawback, however, the work well repays a careful perusal.

Post-Nasal Catarrh and Diseases of the Nose causing Deafness. By Edward Woakes. Illustrated with Wood Engravings. Pp. 224. Philadelphia: P. Blakiston, Son & Co. 1884.

This interesting volume is intended to show the relations that exist between that portion of the upper air tract embraced in the nasal region and the organ of hearing. It would seem from the point of view taken by the author that the otologist must seek for the cause of many aural symptoms in the nervous relationship known to exist between the different regions about the head, especially those between the naso-pharynx and the ear. The extension of catarrhal inflammation from the pharyngeal vault to the ear, *via* the Eustachian, thus seems *not* to be the principal cause of ear disease, as some have supposed.

While the author's style is often unnecessarily involved, and simple facts are frequently made to appear more obscure to the general medical reader than needs be, yet, on the whole, the subject is presented in an entertaining and instructive manner. He has brought into the field of otology the methods of the study of disease which have been already so successfully employed in other departments of medicine, namely, the physiological. The book may be taken, as far as it goes, as a safe guide in the study of aural neuroses.

The present volume is to some extent an elaboration of a former work, in which the nervous mechanism concerning disturbances about the head, and especially about the ears, was discussed. In the introductory chapter there are observations on the correlating and reflex functions of the sympathetic system, which will be found to be broadly instructive, and which go to show that in any successful plan of treatment of aural diseases the local medication must often occupy a subordinate position.

The second chapter treats of the etiology of catarrh, acute and chronic, and what the author designates as the pre-catarrhal state; Chapter III. discusses the mechanism of taking cold; Chapter IV., chronic or post-nasal catarrh, and its sequences; the hygienic management of the catarrhally predisposed is considered in Chapter V.; the diagnosis of chronic catarrh, examination of patients, etc., is taken up in Chapter VI. Other chapters are devoted to acute catarrh, chronic pharyngitis, and the pharyngeal tonsil—their pathology and treatment. Chapters XI. and XII. treat of nasal stenosis.

The chapter on "taking cold" is an admirable exposition of the subject, and should be studied by every one who has to treat nasal catarrhs.

Although the author has made considerable additions to the physiological aspect of the subject, pathological conditions are dwelt on more briefly than seems commensurate with the detailed consideration of the former. Attention is given to the treatment of nasal affections, and some useful suggestions may be found under this head, although the employment of sprays, the nasal douche, and syringe seem to be recommended rather more freely than would be done by most otologists on this side of the water. The treatment of aural affections receives a share of attention, and here Dr. Woakes follows the beaten track. He seems so be a warm advocate of the early incision of the drum-head in acute processes affecting the middle ear, although recommending the procedure with some appearance of caution; this, together with the subsequent free use of the Politzer air-douche and running hot water into the ear seems, to some of us at least, rather heroic. The work on the whole is a valuable contribution to the subject of which it treats, and it should be in the hands of every specialist in this department of medicine, as well as every general practitioner.

Medical Diagnosis, with Special Reference to Practical Medicine. By J. M. Da Costa, M.D., LL.D., Professor of Practice of Medicine and of Clinical Medicine at the Jefferson Medical College, Philadelphia, etc. Sixth edition. Philadelphia: J. B. Lippincott & Co. 1884.

It is pleasant to have to record the appearance of a new edition of Da Costa's well-known medical diagnosis. The work is thoroughly appreciated here, and its translation into foreign tongues shows the estimation in which it is held abroad. The present edition is fully up to date, several not unimportant additions having been made. It is not a work of reference, but rather one that should be studied from beginning to end.

Vorlesungen über Pharmakologie. Von Professor C. Binz, Ord. Professor, Direktor des Pharmakologischen Instituts der Universität Bonn. I. Abtheilung. Berlin: Aug. Hirschwald. 1884. Lectures on Pharmacology. By Dr. C. Binz.

Professor Binz, of Bonn, hardly requires an introduction to the American reader, his original contributions relating to pharmacological subjects having been frequently noticed by the medical press both of England and our own country. The volume before us comprises Part I. of the subject-matter of the lectures delivered annually at the University of Bonn. Two succeeding parts will complete the work. The author has a happy faculty of infusing a new interest into an habitually dry and tedious subject. In this way the book contrasts very favorably with the average Materia Medica and its tiresome enumeration of superfluous details. The pharmacology of Binz, judging from this the first volume, is practical and yet strictly scientific, clear and concise, and yet complete enough to satisfy the demands both of student and practitioner. It goes without saying that the work is fully up to date. We believe that an English translation would find a ready welcome in our country.

The Diseases of Children. A Handbook for Practitioners and Students. By Armand Semple, B.A., M.B. Cantab., M.R.C.P. Lond. Pp. 352. New York: G. P. Putnam's Sons. 1884.

This is a small volume, and presents the subject of pædiatrics in a more condensed form than is the case with the usual treatises. The volume does not strike us as having any great merit aside from its compactness. There is no evidence of originality in thought or method, and we should doubt if Mr. Semple had had a long experience with children's diseases.

In this respect it is in striking contrast with Henoch's work. The author also is not entirely free from misleading statements, as when he describes croupous pneumonia, leaving one to infer that it may attack children at any age, and independently of broncho-pneumonia.

For all this, however, the book is a very fair presentation of its subject, and is in the main trustworthy. It is clearly written and systematically arranged. The publishers have printed it in excellent style.

Medical Annals of Baltimore. From 1608 to 1880, to which is added a Subject Index and Record of Public Services. By John R. Quinan, M.D. Baltimore. 1884.

This volume represents a great deal of painstaking labor, and will be of much local interest and value.

Transactions of the New York Pathological Society. Vol. IV. Based on the Proceedings of the Year 1881, and Supplemented from the Records from 1844. John C. Peters, M.D., Editor. New York: Printed for the Society. 1882.

The New York Pathological Society is one of the best medical societies in this city. Founded forty years ago for "the improvement of its members in pathology, and in the diagnosis and treatment of disease as founded on pathology," it has ever held this object prominently in view, and that it has lost none of its original fervor in the advancement of medical science this present volume of the Transactions bears abundant testimony. The book is neatly printly and strongly bound, and contains more matter of solid worth in its 380 pages than many a more pretentious tome.

The Medical Directory of Philadelphia for 1884. Edited by Samuel B. Hoppin, M.D. Philadelphia: P. Blakiston, Son & Co. 1884.

This little volume contains, besides the list of the regular physicians of Philadelphia, the names of all the homœopathic and eclectic practitioners, and of persons practising medicine without diplomas, but registered under the laws of the State. There are also lists of druggists, dentists, and graduates of recognized veterinary colleges, as well as non-graduate veterinary surgeons and dentists.

The General Practitioner's Guide to Diseases and Injuries of the Eye and Eyelids. By Louis H. Tosswill, B.A., M.B. Cantab., M.R.C.S., Surgeon to the West of England Eye Infirmary at Exeter. London: J. & A. Churchill. 1884.

The author's aim in writing this little book was to give to the general practitioner a manual to which he might refer for guidance in the diagnosis or management of the more common diseases and injuries of the eye. And he has succeeded admirably in his attempt. The book is a model of brevity and clearness of description, and is entirely free from the technical terms and mathematical problems which are usually so confusing to the ordinary reader of works on ophthalmology.

Diseases of the Bladder, Prostate Gland, and Urethra. Including a Practical View of Urinary Diseases, Deposits, and Calculi. Illustrated by Numerous Wood Engravings. Fifth Edition, Revised and much Enlarged throughout. By Frederick James Gant, F.R.C.S., Late President of the Medical Society of London; Senior Surgeon to the Royal Free Hospital; Author of "The Science and Practice of Surgery." New York: Bermingham & Co. 1884.

This, the fifth, edition of Mr. Gant's well-known treatise on diseases of the bladder and neighboring organs comes to us greatly enlarged and revised. Every chapter, indeed almost every page, shows marks of improvement, and of such changes as were necessary to be made in order to maintain the character of the work as a thoroughly reliable guide for the surgeon in dealing with these affections. The author treats not only of the ordinary and more common diseases of these organs, but enters also somewhat at length into the exceptional circumstances in which the surgeon may be placed, and sets down rules, as far as rules can be thus set down, for his guidance in all the straits in which he may find himself. Somewhat over one hundred out of the six hundred pages of the book are devoted to the consideration of urinary diseases and of the nature of the deposits in this fluid. While the author presents in his work but little that is, strictly speaking, new, or which may not be found in one or another of the treatises upon the subjects which it embraces, there are, nevertheless, few books in which one may find so complete an exposition of all diseases relating to the urinary organs as in this. It is, furthermore, by no means a mere compilation, but possesses that peculiar freshness which is a sure evidence that the author writes from personal knowledge, and has not simply clothed the ideas of others in language of his own.

A Study of the Bladder during Parturition. By J. Halliday Croom, M.D., F.R.C.P.E., Physician to the Royal Maternity Hospital; Assistant Physician for Diseases of Women, Royal Infirmary; Examiner in Midwifery in the University, and Lecturer on Midwifery and Diseases of Women, School of Medicine, Edinburgh. Edinburgh: David Douglas. 1884.

The object of this book, containing the substance of several papers communicated to the Edinburgh Obstetrical Society, is to show the extent and manner in which the bladder and its contents are influenced by parturient efforts. The author states that the sources of pressure upon the bladder are three: *a*, Change of shape in the uterine ovoid; *b*, stretching of the cervix; *c*, pressure by the abdominal and other respiratory muscles, *e.g.*, diaphragm, levator ani, etc. The quantity of urine in the bladder does not influence pressure, provided always the point of over-distention is not reached. The minimum pressure is found during the first stage, and amounts to .1 lb., while the maximum occurs during the second stage, and is about 3.2 lbs. on the square inch. The work evidences a large amount of painstaking investigation on the part of the author, but the subject is one in which the ordinary practitioner would take but a languid interest.

Beginnings with the Microscope. A Working Handbook, containing Simple Instructions in the Art and Method of Using the Microscope, and preparing Objects for Examination. By Walter P. Manton, M.D. Illustrated. Pp. 73. Boston: Lee & Shepard. 1884.

This little book will be found very useful for beginners in microscopical study, who are often appalled by the size of the standard treatises on this subject. The author has here given directions for the preparing, staining, and mounting of the objects to be examined, such as are needed by those who have had little or no experience in microscopical work. For advanced students it is of course too elementary, but for beginners it is eminently practical, and may serve as an introduction to the larger works.

The London Pathological Society.

The thirty-fourth volume of the Transactions of this Society is before us. Perhaps our own Society may get some hints from it. It was founded in 1846, and ours in 1844. Its presidents always serve two years, ours generally only one. Its first president, in 1846, was Charles J. B. Williams, ours was Willard Parker, in 1845, although Dr. John A. Swett served as chairman for six months in 1845. Its other presidents have been Charles Aston Key, Peter Mere Latham, Cæsar N. Hawkins, Benjamin Guy Babbington, James M. Arnott, Sir Thomas Watson, Sir William Ferguson, James Copland, Sir Prescott G. Hewitt, Thomas B. Peacock, John Simon, Richard Quain, John Hilton, Sir William Jenner, George D. Pollock, Charles Murchison, Jonathan Hutchinson, Samuel Wilks, John W. Hulk. It always has eight vice-presidents, nine surgical councillors and nine medical, none of whom are vice-presidents; two honorary secretaries, one medical the other surgical; two trustees, and one treasurer. The whole number of members in 1883 was 650, and 27 new members were added during the year.

Dr. Peacock, just deceased, generously bore the whole cost of publishing and issuing a general index to the volumes from 1864–1874, viz., vols. 16–25.

Dr. Edwards Crisp, just deceased, during a long course of years insisted upon the advantage of studying the morbid anatomy of animals, and since 1864 was continually exhibiting specimens, which he had procured from the Zoological Gardens and elsewhere. Dr. Crisp was the pioneer of the London Pathological Society in the study of comparative pathology, and it must have gratified him to witness the establishment by the council, at the suggestion of Dr. J. Hutchinson, of a comparative pathology committee. Another committee has been formed to obtain information respecting the uncompleted cases in the Transactions, which has already reported.

Owing to the large number of specimens offered, a great many could not be received on account of the limit of time at the disposal of the Society, and extra meetings are under consideration.

In 1882 there was £139 balance in the treasury; four hundred annual subscriptions produced £420; twenty-three admission fees, £24; two life fees, £31; two members in arrears, £2. The sale of the Transactions to non-members produced £62, sale of illustrations, £15. Total income, £703.

The Society paid to the Royal Medical and Chirurgical Society for use of rooms, gas, etc., £63; refreshments, waiters, etc., £36; for janitor, microscopes, and lamps, £11; for printing, binding, etc., of Transactions, £194; for supplementary report, 750 copies, £18; for lithography, woodcuts, etc., £126; for stationery, £13; for postage, 3 pence; for secretaries and treasurer, not including stenography, £36; total expenses, £502; balance in treasury, £201.

Opera Minora; a Collection of Essays, Articles, Lectures, and Addresses from 1866 to 1882 inclusive. By Edward C. Seguin, M.D. New York: G. P. Putnam's Sons. 1884.

The articles here collected make a large quarto volume of near seven hundred pages. The author modestly says that "the redeeming feature in the collection will perhaps be the series of observed facts faithfully recorded." The volume has more value than is measured by such an estimate. The articles touch upon nearly the whole field of neurology, and nearly every one contains something of interest or practical value. Expositions of nervous physiology, contributions to neurological therapeutics, and original researches in pathology—especially of the spinal cord—form the leading features of a collection which does great credit both to the author and to American science.

New York and Brooklyn Formulary of Unofficinal Preparations. Published by a Joint Committee of Delegates from the College of Pharmacy of the City of New York, the New York German Apothecaries' Society, and the Kings County Pharmaceutical Society. New York: Publication Office, College of Pharmacy Building.

The great and increasing number of preparations of so-called elegant pharmacy is as annoying and perplexing to the physician as to the pharmacist, and any measures looking toward a reduction of the number are to be welcomed. A committee of delegates from three pharmaceutical societies of this city and Brooklyn have prepared a number of formulæ for the compounding of the more commonly used elixirs, emulsions, and syrups, and it is hoped that the physicians of the two cities will order these preparations only, and not designate on their prescriptions those of any particular house. Such a result is certainly to be desired, and perhaps may be obtained through the wide distribution of this formulary. But the druggists will have to rise betimes in the morning to score a point against the representatives of the manufacturing firms with their smooth tongues and seductive ways. If they succeed in driving these gentlemen from the field they will have earned the gratitude of the entire profession, and will no doubt receive their reward.

Reports of Societies.

MICHIGAN STATE MEDICAL SOCIETY.

Nineteenth Annual Session held at Grand Rapids, June 11 and 12, 1884.

(Continued from No. 24, p. 671.)

In report of the first day's proceedings, by telegraph, of this meeting, abstracts of papers were omitted.

Dr. Donald Maclean, Chairman of the Committee on Surgery, read an interesting report of four cases which had come under his care at the University Hospital clinic. The first case was a lady who presented symptoms of

SYPHILITIC PERIOSTITIS,

but who gave none of the early symptoms or any history of any syphilis either in her own person or that of her husband. The diagnosis seemed to rest between a malignant affection and syphilitic affection. The doctor gave her the benefit of the doubt, put her on large doses of iodide of potassium, and she made a rapid and full recovery.

Some time after she came to the clinic again and presented her little son, about four years of age. The little fellow was bow-legged, and had exostosis of the upper end of the tibia. This patient was put on iodide of potassium and is now reported as quite recovered. The third case was one of

NECROSIS OF THE LOWER END OF THE FEMUR.

In attempting to remove a large piece of necrosed bone with the bone forceps

THE POPLITEAL ARTERY WAS TORN ACROSS.

The hemorrhage was arrested by pressure with the fingers; the necrosed bone was removed and the popliteal artery cut down upon and ligated above and below the site of the injury. The patient did well and made an excellent recovery.

The fourth case was a man of twenty-eight, who in jumping from a train of cars in motion received an injury on the elbow. The arm was firmly anchylosed at the elbow and it was thought best to resect the elbow-joint. A straight incision was made along the back of the arm and when the parts were brought to view it was found that the

RADIUS AND ULNA WERE DISLOCATED BACKWARD AND SOLIDLY ANCHYLOSED

to each other and to the humerus. About one inch was taken off from the humerus, and about an inch from the ulna and radius. The patient made an excellent recovery and has regained motion at the elbow to a large degree—that of supination and pronation. This case is typical of about twenty others which the professor has operated upon at the hospital clinic.

Dr. Charles J. Lundy's paper elicited considerable interest. Dr. Lundy said that within a few years the resources of the aural surgeon had been greatly increased, both by the introduction of new therapeutic agents and by the use of old ones in a new way. In appropriate cases the

SO-CALLED DRY TREATMENT OF CHRONIC SUPPURATIVE OTITIS MEDIA

had proven highly beneficial. All knew that the disease was attended with danger, and many had seen examples of cases, and necrosis of the temporal bone, mastoid abscess, meningitis, cerebral abscess, or death, which occurred as the result of neglected suppurative otitis media. Therefore any system of aural therapeutics which the better enabled us to control and cure this affection was a great boon. Before beginning the use of powders, all remediable complications must be removed. If aural polypus or granulations be present they must be removed or destroyed, and so it was also with removable pieces of necrosed bone, in the mastoid or else-

where. The advantages which the dry treatment of chronic suppurative otitis media seemed to offer were: 1, the constant medication of the parts; 2, the thorough and continuous disinfection of the ear as well as the destruction of micro-organisms; 3, the absorption of the discharges and protection from their irritating properties; 4, protection from atmospheric influences. Some space was devoted to illustration of these points, and while it was not fully settled as to which of these was the most important advantage arising from the use of dry powders, a majority conceded that the destruction of the micro-organisms and the protection from atmospheric influences were the strong arguments in favor of the dry treatment. It could not be claimed that powders should be used to the exclusion of remedies in other forms, and they were counter-indicated at times. In certain cases they proved a failure, and sometimes did harm instead of good. While no definite plan could be laid down for the management of individual cases, yet some rules could be formulated for our guidance in a general way.

The so-called dry treatment would seem to be contra-indicated under the following circumstances: First, when the discharge is so profuse that the powder becomes supersaturated before it has had time to exert any beneficial influence; second, when granulations or polypi exist the dry treatment should not be employed until these bodies have been destroyed or removed, although powdered boracic acid would cause absorption or destruction of these in a few cases; third, when the disease is complicated by caries or necrosis of the temporal bone; fourth, when mastoid abscess is present or suspected; fifth, when there is good reason to suspect the presence of meningeal or cerebral complications. The remedies which might be used were numerous but the author had confined himself to few. Wyeth's pure boracic acid was free from irritating properties and a favorable remedy with him. Boracic acid, one part with seven parts of resorcin, formed a valuable combination. Bismuth and perchloride of mercury he sometimes used, especially if eczema of the auditory canal existed. Astringents could be combined with the boracic acid if desired. It was of great importance to cleanse the ear thoroughly before using the powders. After the lapse of one, two, or three days, when the powder becomes moist, it should be removed, and the ear filled with fresh powder. Cases were reported showing some very remarkable cures from the use of remedies in dry form, especially from boracic acid. A paper on

EXPERT TESTIMONY AND COMPENSATION,

from the pen of Dr. Samuel P. Duffield was a well-digested, carefully written essay.

Starting with the German motto from Lessing, *Wer viel weiss hat viel zu sorgin* ("He who knows much has much to care for"), he claimed that Lord Bacon uttered a truth when he said, "The greatest trust between man and man was the trust of giving counsel," and if, said the essayist, he were in our profession and called to the witness-stand, in Wayne County especially, he would have probably added, "and no counsellors are so poorly paid." This province of giving counsel cannot be reserved by the legal fraternity alone, they are not the only Gamaliels at whose feet the young Sauls of Tarsus must learn wisdom. A lawyer can *cram*, but he cannot *counsel* on *our* specialties. Physicians as counsellors in their departments of knowledge are denominated "experts." So far they seem to have been expert in telling all they know and *not expert* at getting *paid* for it.

He described the ancient law, which was intended to prevent the perfidy of advocates, and showed how during the time of Claudius it was so modified that advocates, were permitted to receive any sum up to 10,000 sesterces, or about $400, and thus was paved the way for that amendment under Claudius which recognized the fact that professional services have created something more than imperfect obligation on the part of the recipient, and entitled the practitioner to his "quiddam honorarium," even through the intervention of the magistrate. Such was the high standard affixed to the exercise of a liberal profession among the most polished people of antiquity. The author of the paper gave two sets of cases, viz.: 1, cases favoring extra compensation; 2, cases denying the right to extra compensation—reference being had to Buchman *vs.* State of Indiana, 59 Ind., 1; U. S. *vs.* Howe, 12 Central Law Journal, 193; and for American cases denying the right of compensation reference was had to 53 Alabama, 389, before the Supreme Court of Alabama, *ex parte* Dement.

Dr. D. also reviewed the article by Rasselle Johnson which appears in the June number of the *North American Review*, showing his fallacious definition of the word witness in that article, is not consistent, "for the expert is not testifying of facts," but is acting as an interpreter by making legible that which was written in blood, or paint, or other stain upon the clothing. He stands as Daniel at Belshazzar's feast, interpreting the mysterious, and to the mass the unknown characters which shine out in the testimony, but which *cannot* be interpreted by the jury. Called by opposing counsel rather than by the judge, answering alternately yes or no to contradictory hypothetical questions ingeniously based on *selected* facts in testimony, and so with show of science, falsely so called, leaving the jury more befogged than ever. *True science* asks a different definition from this, and indignantly appeals from such data.

It can never be reached without distinct and honest co-operation between legal and medical experts. The bar must reach forth an *honest* hand to the physician and he must conscientiously respond; both must be willing searchers for that gem which is the crystallization of years of medical experience and science realizing the truth of Goethe's words, *Die weisheit ist nur in der warheit* ("Wisdom is only in truth").

President Dr. A. F. Whelan, of Hillsdale, called Vice-President H. Tupper to the chair, and read his

ANNUAL ADDRESS.

He reviewed the history and progress of medicine, and said it had done more to break up dark faiths by building up the minds of the people, and despite the opposition and hindrances that have always been in the way it will be triumphant. He closed with an appropriate tribute to the memory of Drs. Jas. H. Jerome and Wm. Brownell, deceased.

Dr. T. A. McGraw, of Detroit, read a paper of great practical value on

DIAGNOSIS OF TUMORS.

He thought that all abnormal growths were the result of irritation or a slow inflammatory process. Hypertrophy was the result of increased nutritive action and is not a neoplasm. He discussed quite extensively the nature and pathology of tumors. He had made a thorough study of cystic tumors of the breast, and thought that they should be removed entirely as soon as discovered, and if they showed a tendency to return the entire breast should be removed. He thought that all tumors had better be taken out promptly and thoroughly. He had often known apparently innocent growths to take on a malignant action from local irritation. He believed that warts and moles were often irritated until they became malignant. He thought that the better way to remove a tumor was to use the knife.

Dr. A. B. Palmer, of the State University, read a paper on

PROSTATIC HYPERTROPHY AND URINARY OBSTRUCTION, ITS TREATMENT WITHOUT CATHETERISM,

which, from the simplicity and to many the novelty of the method, attracted particular attention.

After referring to the frequency of prostatic enlargement in advanced life and to the occurrence of what

Spiemlart calls the "catheter period," which means a period of such obstruction to the passage of the urine in which the bladder is not completely emptied, an irritation of the urinary organs of a somewhat decided character occurs, and which also implies that from that time onward the catheter must be a constant companion and one likely to be brought into frequent use; and after further referring to the great unpleasantness and not infrequent dangers of its introduction — the "catheter fever" and the still more frequent shock—the method of procedure in the management of cases was described as follows: "The urethra is to be filled with urine as in an effort at micturition. The penis is then grasped by the hand of the patient and the urethra is pressed upon near the glands or in some part of its course sufficient to introduce the flow; and then by straining, as in an attempt to forcibly empty the bladder, the distention of the urethra is produced. This distending pressure is gentle, steady, diffused, and painless, and may be applied and sustained at will, and in a majority of cases, if daily repeated for a time and afterward occasionally, and if it is done thoroughly, and especially if commenced at an early period of the obstruction, it will overcome this form of stricture effectually and without irritation or danger."

A case as a specimen of many others was given in detail as illustrating the efficacy of the measure.

The paper concluded with the statement that from sufficient experience the efficacy and value of this method had been demonstrated and it was strongly commended to the attention of the profession.

In compliance with a resolution previously made by Dr. Pratt and adopted by the Society, the President appointed a committee to nominate officers for the ensuing year, except President. The committee was composed of Drs. William Brodie, H. McColl, S. H. Clizbee, G. K. Johnson, and E. P. Christian.

Dr. G. K. Johnson's paper was on motion, made the special order for 9 A.M. next day.

Dr. E. L. Shurly as one of a committee appointed by the U. S. Climatological Association to collect data of

NATURAL CAUSES PREDISPOSING TO PHTHISIS PULMONALIS,

appealed to the members present and the profession throughout the State to assist him by reporting to him on blank cards which he distributed to those present.

As adjournment would take place before all the papers offered could be read, on motion of Dr. Ward, authors of papers were allowed to read them by title, and when so read they were referred to the Publication Committee.

STERILITY IN WOMEN.

Dr. J. H. Carstens, of Detroit, read a paper on "Sterility in Women," calling attention to the frequency of the disease and the great importance of this condition to the State, and especially to the individual so afflicted. That in order to understand the cause and cure of sterility it was best to consider the essentials of pregnancy. Then we come to the conclusion, that sterility can be cured by absence of disease of ovaries, Fallopian tubes, displacements of uterus, strictures and occlusions of uterine canal or of the vagina. These were the causes in women, but the husband was sometimes to blame and should never be neglected. Especially should we be guarded in our prognosis and not promise a cure, as we never could be positive that pregnancy would occur, even after the cure of the diseases which often cause sterility.

SECOND DAY—MORNING SESSION.

Meeting called to order by the President. Calling of the roll and reading of the minutes was dispensed with.

Dr. Breakey, as chairman of the Committee on Necrology, rendered a verbal report, and asked further time to complete his written report and refer the same to the Committee on Publication. Granted.

Report of a case of

PERINEPHRITIC ABSCESS,

with remarks, by Dr. George K. Johnson, of Grand Rapids, was next called for and read. This was a case occurring in a man twenty-two years of age, whose illness was marked by symptoms seen in typhoid fever, which symptoms partially abated. Soon, however, an indefinite ailment, characterized by weakness, want of appetite, loss of flesh, feeble pulse, cachectic fever, and pain in left iliac and lumbar region, led him to again consult the doctor. In a word there was present the group of phenomena which signalized hectic or pyogenesis. Pain in the left costo-iliac space had come on and was increased by pressure. A feeling of weight in left flank and left upper abdomen was complained of, but no pain in genital tract or groin. Urine voided frequently, loaded with pus, but without blood, mucus, or casts. Left half of abdomen distended with fluctuating tumor, easily traced. Hypodermic needle passed into the tumor withdrew a drachm of pus and confirmed the diagnosis. The body forces fast waning and danger that the cyst would rupture and pour its contents into the cavity of the abdomen, the doctor decided to at once aspirate the tumor. Passing the needle at the external margin of left rectus, two inches below the level of the umbilicus, he removed eighty-four ounces of pus. Within a few hours relief came, fever left, and pain vanished. On the second day the temperature of the patient reached 100° F. in the morning and 104° F. in the evening, and on the fourth day the temperature was 99½° F. in the morning, and 104½° F. in the evening, when it reached its climax, the patient having, though restless, suffered no pain or swelling of the parts since aspiration. Six days after the aspiration some fulness appeared over the site of the tumor, and after a few days there was found to be considerable reaccumulation of pus. But the discharge by the urinary conduits was so free that no further accumulation took place and all tumefaction slowly but steadily disappeared. Three months after aspiration the patient seemed entirely well, appetite, strength, flesh, and spirits were fully restored. The urine was normal, and all traces of the tumor was gone.

The author closed his paper by a somewhat comprehensive and very instructive review of the somewhat meagre literature of the class of cases to which the one reported was typical, gave a careful history of the pathology and course of the disease, calling attention to important points in its diagnosis, so essential to the practitioner, who is often betogged for want of proper description by authors of the symptoms and signs of probable and possible value in localizing and diagnosing perinephritis and perinephritic abscess.

Dr. E. P. Christian read a paper on "Placenta Previa," which was referred to the Publication Committee.

OFFICERS FOR THE ENSUING YEAR.

The Committee on Nominations rendered their report recommending officers for the ensuing year as follows: *Vice-Presidents*—J. Perkins, Owasso; J. M. Cook, Muskegon; Gordon Chittock, Jackson; Case Brumme, Detroit; *Secretary*—Geo. E. Ranney, Lansing; *Treasurer*—A. R. Smart, Hudson; *Judicial Council*—F. K. Owen, Ypsilanti; C. V. Tyler, Bay City; H. M. Clou, Lapeer; *Delegates to American Medical Association*—Wm. Brodie, Detroit; H. B. Baker, Lansing; J. H. Bennett, Coldwater; J. B. Book, Detroit; W. F. Breakey, Ann Arbor; C. Brumme, Detroit; J. H. Carsten, Detroit; S. H. Clizbee, Coldwater; L. Connor, Detroit; E. S. Dunstan, Ann Arbor; S. P. Duffield, Dearborn; S. S. French, Battle Creek; A. D. Hogadorne, Lansing; H. O. Hitchcock, Kalamazoo; G. K. Johnson, Grand Rapids; D. Maclean, Detroit; H. M. Cole, Lapeer; F. M. Oakley, Ypsilanti; F. K. Owen, Ypsilanti; A. B. Palmer, Ann Arbor; F. Pratt, Kalamazoo; G. E. Ranney, Lansing; W. F. Sigler,

Pinkney; H. A. Shank, Lansing; E. Snow, Dearborn; C. F. Southworth, Monroe; T. H. Tupper, Bay City; C. V. Tyler, Bay City; D. C. Wade, Holly; A. F. Whelan, Hillsdale; Chas. Shepard, Grand Rapids.

The report of the committee was adopted.

The Society next proceeded to ballot for President, with the following result: Whole number of votes cast 196, of which Donald Maclean received 126; S. S. French, 63; scattering, 6.

Dr. Maclean was thereupon declared elected.

The usual votes of thanks for the many courtesies extended by the physicians and citizens of Grand Rapids and to the retiring officers were then passed.

Dr. Miles, of Port Huron, extended an invitation to the Society to hold its next annual meeting at Port Huron. Carried.

Dr. A. W. Nichols, of Greenville, read an interesting, practical, instructive paper on "Nasal Catarrh," which was referred to Committee on Publication.

GRANULATED LIDS.

Dr. Eugene Smith, of Detroit, read a paper on "Granulated Lids" and related a case in which he had used jequirity with good effect. He uses a three per cent. solution, and applies it two or three times a day for three or four days, and then follows with boracic acid. He thinks this remedy is well adapted to old chronic cases where there is no purulent secretion.

MISCELLANEOUS BUSINESS.

A paper by Dr. R. J. Kirkland on "Chronic Catarrhal Otitis," one by Dr. A. R. Smart on "Therapeutics of Dysmenorrhœa," one by Dr. D. W. C. Wade on "Uterine Displacements," were all interesting, able papers, and were referred to the Committee on Publication.

Over two hundred physicians were in attendance, upward of eighty of whom were elected members at this meeting.

The Society transacted considerable miscellaneous business pertaining to local and personal matters, and adjourned till the second Wednesday of June, 1885.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CONFERENCES ON HEALTH — DOMESTIC SANITARY ARRANGEMENTS OF THE METROPOLITAN POOR—DOMESTIC SANITATION OF RURAL DISTRICTS—INDUSTRIAL DISEASES—INFECTIOUS DISEASES—DISPOSAL OF THE DEAD.

London, June 14, 1884.

What may be termed the Health Congress began on Monday last, June 9th. This consists of a series of conferences organized by a joint-committee of the following bodies: Society of Medical Officers of Health, Sanitary Institute of Great Britain, Parkes Museum of Hygiene.

The meetings have been thrown open to all visitors to the Health Exhibition. No one will be sanguine enough to believe that a tithe of the sightseers who visit the Exhibition will find their way into the conference room, and patiently listen to the reading of the papers; but the chief end and aim of the meetings will be gained if, through the publicity given to them, the public gets a more intimate acquaintance with, and places a deeper trust in, the science and practice of hygiene. Many of the subjects discussed, and propositions brought forward, have long been familiar to sanitarians, but to ordinary medical practitioners, who are so largely occupied in the treatment of disease, they are probably less well-known. In any case the threshing out again of health topics cannot fail to be beneficial.

The ball was opened on Monday by the reading of a paper on "Domestic Sanitary Arrangements of the Metropolitan Poor," by Dr. Tripe. Dr. Tripe is a well-known sanitarian, and as the medical officer of health to a populous parish in the East end of London, is well qualified to speak on the subject from actual observation. He remarked that the chief defects arose from want of a proper water-supply. This, of course, led to defective drainage and escape of sewer-gas from unflushed drains and dried-up traps. Unemptied dust-bins were also great nuisances.

Mr. Ernest Turner, who is an architect, and consequently approached the subject from an architectural standpoint, followed with a paper on "The Improvement of the Sanitary Arrangements of Metropolitan Houses." It is satisfactory to find that a few architects are beginning the study of hygiene. A whole number of The Medical Record could easily be filled with accounts of unsanitary arrangements perpetrated by architects in the past. I could testify to a good many from personal observation. It is not all the fault of the "jerry-builders." A West end mansion I frequently pass had the soil-pipe imbedded in the wall of the dining-room, and constructed of such thin lead that it gave way and caused a leakage of sewage through the wall, which continued for some time. When the cause was at last discovered, the owner determined to do, what in fact should have been done at first, viz., place all the drain-pipes outside the building.

On Tuesday the conference was continued by the reading of a paper by Dr. George Wilson on "Domestic Sanitation of Rural Districts." Dr. Wilson quoted the report of the agricultural commission of 1867, which showed that one-third of the rural homes of England were unfit to be used as dwellings, and that therefore 700,000 hovels ought to be pulled down. In many villages he knew himself half the cottages contained only two sleeping-rooms, and about ten per cent. only one, and his district (Warwickshire) was considered by the commission better than many. He said the poverty of the owners and the low wages earned by the occupiers were obstacles to improvement. Dr. Wilson advocated for rural districts the adoption of the "pail system" or else ash-pit closets.

Mr. Boulnois, civil engineer, then read a paper on "Sanitary Houses for the Working Classes in Urban Districts." He condemned the erection of huge blocks, also basement rooms. Flat roofs were good for gardens or drying grounds, also for escape in case of fire. He urged the advantages of a constant water-supply.

On Wednesday, a paper on "Industrial Diseases" was read by Dr. Bristowe, F.R.S., Physician to St. Thomas' Hospital, and Medical Officer of Health for Camberwell. The causation and prevention of industrial diseases is a subject to which sanitarians have devoted a good deal of attention of late years, and Dr. Bristowe made the most of his subject in the limited time allotted him, dwelling in succession on the chief diseases caused or aggravated by different trades, and the modes of prevention that may be adopted.

On Thursday an interesting paper was read by Dr. Thursfield on "The Spread of Infectious Diseases through the agency of Milk." Dr. Thursfield remarked on the great increase in the consumption of cow's milk both by adults and infants—in the latter case, through the unfortunate increase in the number of women physically incompetent for lactation. It was presumable that in many cases of disease from milk, the source had not been suspected, but making allowance for doubtful cases, he thought it might be accepted as a fact that enteric and scarlet fevers had been repeatedly disseminated by milk, and there was also very strong evidence as to the spread of diphtheria through the same agency. He considered

that the boiling of milk practically conferred immunity from infection. Dr. Thursfield enumerated the restrictions it was desirable to place on the sale of milk, and observed that an urban sanitary authority should have the power to stop the sale of milk sent from any particular farm, pending investigations, but that there should be liability for compensation if the step proved unnecessary. In the discussion which followed the reading of the paper, Dr. De Chaumont, professor of hygiene at Netley, assented to the views expressed as to the frequent conveyance of infectious diseases by milk, but stated that the views received here did not find acceptance abroad, and that some of his French and German friends looked on the whole thing as a gigantic joke. Dr. Corfield read a paper on "The Spread of Infectious Diseases through other Agencies than Milk."

On Friday the "Notification of Infectious Diseases" was discussed in two papers by Drs. Alfred Hill and Alfred Carpenter, respectively. Dr. Hill urged its importance as the only means by which news of an epidemic could be obtained, and was of opinion that it should be compulsory on all medical men to notify. Dr. Carpenter considered notification a moral duty to the State, and that it was the duty of the State to enforce it. The chairman, Earl Fortescue, spoke of the danger of interfering with either personal liberty or the rights of property, and in summing up the discussion which followed the reading of the papers, as on previous days, said he thought a case had been made out for notification, but it appeared to him that the duty should be laid on the householder rather than on the doctor. With this opinion the bulk of the profession will concur. It is mainly the professed sanitarians who wish to compel the doctor to notify. Ordinary practitioners are against it. It would no doubt be a great lightening of the labors of medical officers of health, but at the expense of an increase of worry and responsibility to the actual practitioners. It is significant that out of about 120 medical men at Brighton, 100 have petitioned against notification being made compulsory in that town.

The subject for to-day is the "Disposal of the Dead," on which Mr. Wynter Blyth, medical officer of health for Marylebone, will read a paper. Mr. Eassie will follow with one on "Cremation," of which he is an advocate.

SUCCESSFUL LOCAL APPLICATION OF ETHER TO MUCOUS MEMBRANE OF BLADDER FOR NEURALGIA OF THAT ORGAN.

To the Editor of The Medical Record.

Sir: Apropos of etherization by the rectum, permit me to mention another channel through which I have introduced ether into the economy. In two cases of severe and obstinate neuralgia of the bladder, which had resisted morphine, belladonna, hyoscyamus, fomentations, in fact, almost everything recommended in the treatment of this distressing affection, I injected into the bladder ether, gtt. x., in water, ʒ ij. Any detailed account of the cases your valuable time and space will not permit and, therefore, I can only add that *within one minute* the ether was perceptible in the breath in both instances, and within five minutes' time there was perfect relief from pain which had been previously most severe. The conclusions were verified a number of times.

The mucous coat of the bladder being non-absorbing, as some authorities claim, how could the ether pass so quickly into the circulation? Has ether ever been used in this manner before and what have been the results. I have been unable to find a precedent for its use in the literature upon the subject.

Very respectfully,

John Parmenter, M.D.

192 Georgia Street, Buffalo.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 22 to June 28, 1884.

Clements, Bennett A., Major and Surgeon. Ordered to relieve Major Jos. P. Wright, Surgeon, of his duties as Attending Surgeon at the Leavenworth Military Prison, Fort Leavenworth, Kansas. Major Wright, on being relieved, ordered to report to the Commanding General Department of Texas, for assignment to duty. S. O. 144, par. 7, A. G. O., June 21, 1884.

Dickson, John M., Captain and Assistant Surgeon, assigned to duty as Post Surgeon, Alcatraz Island, California. S. O. 71, par. 3, Headquarters Department of California, June 19, 1884.

Girard, A. C., Captain and Assistant Surgeon. Granted leave of absence for six months, with permission to go beyond sea. S. O. 148, par. 11, A. G. O., June 26, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending June 28, 1884.

Knight, J. S., Surgeon. Placed on Retired List.

Whiting, R., Passed Assistant Surgeon. Detached from U. S. S. Vermont, and ordered to Marine Rendezvous, New York.

Babin, H. J., Surgeon. Detached from Marine Rendezvous, New York, and ordered to U. S. S. Minnesota.

Wells, H. M., Surgeon. Ordered for examination preliminary to promotion.

Lumsden, G. P., Passed Assistant Surgeon. Detached from U. S. S. Pensacola and placed on waiting orders.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 28, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.

June 28, 1884	5	16	56	6	186	35	0	0
Deaths.								
June 21, 1884	0	5	12	4	29	15	0	0
June 28, 1884	2	5	17	5	29	15	0	0

The Validity of a Life Insurance Policy.—An important insurance decision has recently been rendered in the United States Supreme Court, sustaining the validity of a policy although statements were made by the insured which were not absolutely true. He was asked among other questions whether he ever had had asthma, scrofula, or consumption, and he answered no. After his death it was found that he had one of these diseases in an incipient form at the time of making this answer, but was unaware of it himself. This condition of the case was held to avoid the policy by the trial court and an appeal was taken from the decision to the Supreme Court, where it has just now been reversed. The latter court stated that if the insured had no reason to believe that he was afflicted with the disease at the time of making the application, he should not be precluded from the advantages of the policy.

Actinomycosis.—At the last meeting of the London Pathological Society, Mr. Frederick Treves gave a further account of his supposed case of actinomycosis. The disease began two years ago after erysipelas. It commenced with a swelling over the lower jaw, on the left side, which increased and was excised. The wound would not heal and an ulcer remained. The glands at the back of the neck then enlarged, and nodules appeared over the chest, about thirty in all. As each nodule appeared under the skin it developed a pustule; ulceration and fungation followed. Mr. Treves said that although no fungi were found, and no communication with animals traceable, he was inclined to call it actinomycosis, as Ponfick's description was so accurately realized. Mr. Treves removed several of the nodules and the patient seemed to do well, but a second operation was succeeded by great weakness and the patient died in a month. Secondary deposits, in the form of round yellowish nodules, were found in the lung, liver, spleen, and kidney. Mr. Watson Cheyne had examined the organs, but had been unable to discover any micro-organisms or cultivate any micro-parasites. The structure resembled alveolar sarcoma. Clusters of cells were arranged in a plexiform manner with some connective tissue. Mr. Treves remarked that the suppuration of each nodule, soon after its appearance, was remarkable, and so was the protracted character of the malady. He considered that the diagnosis at times lay between scrofula, cancer, farcy, and actinomycosis.

Mr. Hulke, who had seen the patient during life, thought the case resembled farcy.

Mr. Watson Cheyne remarked that as the farcy organism could be easily cultivated, and cultivation experiments had produced negative results, farcy might be excluded. He thought the case was one of carcinoma.

Mr. Treves remarked that the case was slower than one of farcy.

Contagious Diseases Acts.—The total repeal of the Contagious Diseases Acts is likely to be soon accomplished. Since the adverse vote of the House of Commons last year the action of the compulsory clauses has been suspended, and the Secretary for War now proposes to bring in a bill for the abolition of the remaining provisions of the acts. There is good evidence that venereal affections have increased during the last year, and should the new bill pass, a further increase may be expected. Public opinion, though, will not support the acts, and the accounts of how the French system works have done a great deal to disgust every one with all systems of compulsion.

Report of a Case of Multiple Pregnancy; Cæsarean Section.—The following interesting case was read before the Montgomery County, O., Medical Society by Dr. C. H. Humphreys, of Dayton, O., and created quite a sensation: "The rarity of Cæsarean section always lends interest to every new case. I was recently the accoucheur on an occasion requiring its performance, and beg leave, therefore, briefly to report it. On a Sunday evening, some three weeks ago, a gentleman entered my office, and with some hesitation requested my attendance upon the subject of this sketch in confinement, who was a rather handsome young primipara, unmarried, a native of Massachusetts, and since last summer a resident of this city. Labor began the night previous, and about 9 A.M. a living fœtus was born without assistance. The pains continued unabated, however, and toward evening it was decided medical aid should be called. Upon arrival I made a vaginal examination and diagnosed multiple pregnancy. As well as I could determine, the dystocia was caused by a transverse presentation. The patient showed much exhaustion and was constantly changing her position in bed. Version by external manipulation was fairly tried, but this procedure proved an entire failure. I did not think introduction of my hand within the uterus to perform version possible, and did not attempt it. Her condition contra-indicated such violence. At about 6 P.M., the patient's condition being unpromising, and it being evident that something must be done without delay, I determined in my dilemma to make at once Cæsarean section. Accordingly preparation was hastily made, and the patient placed on an operating table. She at first declined an anæsthetic, but finally consented to the use of ether, which acted well. Commencing near the umbilicus, I made an incision about three inches long in the median line and opened the abdominal cavity. The uterus presenting, it was incised to correspond. A dead fœtus with membranes ruptured lay transversely and was removed, the placenta separating with but little hemorrhage. Two others were removed with envelops entire, and each had separate placentæ. The umbilical cords were duly tied and cut, and efforts at resuscitation made, which finally were successful. The uterine wound was closed by the continued suture of fine silk. Some delay was caused by hemorrhage from the divided uterine vessels, which finally was arrested by hot water. The peritoneum was sponged clean and dry with carbolized warm water, and the incision closed by deep interrupted sutures of strong silk. No dressings were applied. Duration of operation, about thirty-five minutes. Before the question may be raised as to whether this was a justifiable operation, permit me to 'let the cat out,' and confess that this patient was only a cat! And I might also here venture that the result of my operation ought to vindicate our profession from the charge occasionally made against some of its members with derision by some evil-minded laymen, that 'he cannot doctor a cat!' I have only to add that pussy was carefully nursed by watchful little friends and made a speedy recovery. The abdominal sutures were removed a week afterward, and union was found to be complete. The kittens that were 'untimely ripped from their mother's womb' died of inanition within the week. The first-born yet survives, however."

The Dram-Shop Act not Applicable to Druggists in Illinois.—A section of what is called the Dram-Shop Act, passed not long since by the Illinois Legislature, provides for the filing of a bond for $3,000 by any sellers of intoxicating liquors, and it has been a question whether this applied to druggists who had permits to sell for medicinal, chemical, and sacramental purposes. A case of this sort was tried in Vermilion County, and it was held that druggists were bound by the provisions of the law like all other persons. An appeal was taken, however, from this decision, and the Supreme Court of Illinois has just reversed this decision, holding that druggists are exempt from the bond. It was also decided in the same case that where a village ordinance prohibits the sale or giving away of intoxicating liquors within the village limits, but allows druggists to sell for purely medicinal, chemical, and sacramental purposes, if there is no provision made for a written permit, that the ordinance itself is a permit to all the druggists in the village, and they will be protected in selling.

The Druggists and the Drug Appraisers.—Charges have been preferred against the Appraiser's Department of the Custom House in this city by a number of firms importing dye-stuffs, drugs, and chemicals, charging that they are hampered and injured in their business by the unjust discriminations of the officials. A memorial has been prepared and sent to Congress in which the importers say that charges of undervaluation are continually made against their invoices, which charges have been shown to be baseless, and that as a result they are injured in business and reputation. The memorial states "that while carrying on their said business, and in all respects, as they believe, complying with the laws, they are continually obstructed, hindered, delayed, and embarrassed in their efforts to get possession of their goods after they have passed into the hands of the customs authorities at this port, and that such delays and hindrances amount to a serious interference with business, causing much loss

and damage. . . . That it frequently happens that goods needed for speedy delivery are held for one, two, or three months, so that in many cases the importer is prevented from delivering to purchasers according to contract, and is often in this way subjected to heavy loss. That the undersigned have not only been subjected to the delays and annoyances aforesaid, but damaging reports of fraudulent undervaluations have been invented and circulated concerning persons in their trade and business; that such reports, though often indefinite and vague, amount to an imputation of fraud, and wrongfully and unjustly throw suspicion on the business and transactions of the undersigned and others, and that such charges are made by United States officers, and have appeared and been published in their official reports." The memorial concludes by requesting that an investigation be had into the whole matter, under the direction of Congress. The following firms are the signers of the document: W. M. Pickardt & Kuttroff, 98 Liberty Street; F. Bredt & Co., 26 Murray Street; Lutz & Morius, 15 Warren Street; J. C. Bloomfield & Co., 11 Dey Street; Leisel & Halbach; W. J. Matheson & Co., 20 Cedar Street; Geisenheimer & Co., 22 Liberty Street; E. Selbach & Co., 48 Cedar Street; Schulze, Berge & Koeck, and Baumig, Bissell & Co., 22 Dey Street. It is thought probable that an investigation will be ordered.

"A Good Generall Rule of Physyke."—Some one has hunted up from an old book called "Hundred Mery Talys" the following interesting prescription: "A certayn artificer in London there was, whyche was sore seke and coulde not well dysgest his meat. To whom a physicion cam to give hym councell, and sayd that he must vse to ete metis that be lyght of digestyon and small byrdys, as sparowes, swalowes, and specyally that byrd which is called a wagtayle, whose flessh is meruelouse lyght of digestyon, bycause that byrd is euer mouying and styrynge. The seke man, herynge the phesicion say so, answered hym and seyd: 'sir, yf that be the cause that those byrds be lyght of dygestyon, then I know a mete moch lyghter of dygestyon than other sparow, swallow, or wagtaile, and that is my wyues tong, for it is neuer in rest, but euer meuying and sterryng.' By this tale ye may lerne a good generall rule of physyke."

A French Compliment for Richmond.—A Dr. Bougarel, who states that he was for four years in charge of the pest-house in Richmond, Va., sends to *Le Concours Médical* a very pleasing account of the state of medical education in that city. There are, he says, one medical college and two hospitals, one for the blacks and one for the whites, but the medical students never set foot in the hospitals, gaining their practical knowledge in a college clinic. At the end of two years (the writer might have added of five or six months each) these young gentlemen start out armed with the diploma of doctor, written in Latin, with the Hippocratic oath printed on the back. Two of these doctors are assigned to service in the hospitals, and there, under the eye of the chief surgeon, they undertake the most hazardous operations. They do not appear to be very successful, however, for the veracious writer states that almost all the patients die, adding by way of explanation that "human life counts for less than nothing in America." Those who survive the operation are by no means out of the woods, for they are then turned over to the tender mercies of the nurses, who apply the dressings in a most elementary way without observing the least precautions. The doctors in the meanwhile are walking about town with their hands in their pockets. They do, however, as a matter of form, visit the wards once a day, sometimes in the morning, sometimes in the evening, as suits their convenience. But in Philadelphia, Dr. Bougarel continues, medical education is even more simple. The candidate begins by paying down twenty-five dollars, undergoes a very superficial examination, and leaves the college fortified with a diploma, in virtue of which he may henceforth assassinate with impunity those whom his attainments attract to him. The writer closes with the assurance that his readers may rely absolutely upon his statements, for he has cited only such facts as he has himself observed. Notwithstanding the outrageous exaggeration of Dr. Bougarel's letter, it must be confessed that his account rests upon some foundation of truth, at least of what was truth at the time of which he writes.

A New Method in Adherent Placenta.—Dr. W. W. Jaggard writes to the *Chicago Medical Journal*: "The New York Medical Record, May 17, 1884, alludes to a report in the *Clinique*, by Dr. J. Feld, of Kansas City, on 'A New Method in Adherent Placenta.' In six cases of adherent placenta, the life of the woman was saved by pumping cold water through the umbilical cord. Although The Record is in error in its denomination of the method as a new one, it deserves credit for calling attention to a very old and very excellent procedure. The injection of cold water into the umbilical vein in *post-partum* hemorrhage and adherent placenta was ably advocated and extensively practised by Mojon (1826), Kilian, and others. The umbilical vein is divided transversely, a tube or quill fastened securely in the proximal extremity, and cold water injected, slowly and carefully, into the placenta, by means of an ordinary syringe. The cold water, forcing its way into the placenta, distends that organ to twice its original volume, escaping through the lacerated utero-placental vessels, bathes the endometrium, and stimulates the uterus to powerful contractions, usually resulting in the total separation and spontaneous expulsion of the after-birth. Stoltz and Rombach (1855) have extolled most highly this measure, while Linéard (1875) claimed that the injection of 150 grammes of pure cold water into the umbilical vein was 'the best, most reliable, and least dangerous expedient in all cases of *post-partum* hemorrhage or adherent placenta.' At present this method is extensively practised in Germany, more particularly in Bavaria. Scanzoni, in Würzburg, practises this method exclusively."

Medicine and Medical Men in Denmark.—The coming meeting of the International Medical Congress, to be held in Copenhagen, makes Denmark just now a point of professional interest. The *Lancet* is publishing a series of letters relative to this question, from one of which we extract the following: "In proportion to the population of Denmark, the number of Danish medical men is large, as is the case in almost every country. In the city of Copenhagen, where the inhabitants number some two hundred and fifty thousand, there are more than three hundred and fifty doctors, of whom about two hundred and fifty are general practitioners, the remainder being mostly either young medical men in the hospitals or elderly gentlemen who have retired from practice. There is no difference made between surgeons and physicians, inasmuch as all have to pass the same examination at the University, and this gives the whole profession a uniformity which does not exist in England. With the exception of a few specialists and surgeons, the majority of medical men are general practitioners, and it is customary for each household to have its own doctor, who, in return for his services, receives a fixed annual fee varying in amount according to the means of the family. This arrangement is attended with its advantages and disadvantages, but is generally thought satisfactory to both parties concerned. It tends to make the incomes of the medical men more fixed and permanent, and it affords the patient the opportunity of calling in his doctor for what may be either serious or trifling complaints. As an illustration of this latter, there is a trustworthy story of an elderly lady sending for her doctor late at night because she was troubled in her mind as to whether it would be prudent for her to eat a baked apple the first thing in the morning. In Denmark medical men hardly ever attend normal deliveries. These cases are left entirely to midwives, who

have to attend a midwifery school at the Lying-in Hospital for the greater portion of a year, and then to pass an examination previous to being allowed to practise. Of late, however, there has been a movement in the medical profession in favor of general practitioners undertaking these cases, though as yet the movement has not met with much success. A change which would probably meet with most approval would be for educated ladies, qualified as midwives, to undertake these cases. At present their number is small. The social position of members of the Danish medical profession is almost the same as in England, excepting that there are very few who have large incomes from their practice. Fees, as in England, are here considered only a *pium désideratum*, and are as a rule much smaller. Consequently a man with an average income is only tolerably well off, but as wealth is more equally divided in Denmark than in England, a small income has not the same significance. While one meets with few millionaires, but few paupers are to be seen. One observes in the streets of Copenhagen nothing approaching the luxury in the outward appearance of life which prevails in England, but at the same time one does not encounter rags and misery, and such a thing as death from absolute starvation has hardly ever been heard of. The result of this financial equality is that money has not the same importance attached to it as in England, consequently that perpetual struggle to keep up appearances (an expression which does not exist in the Danish language) is unknown here, a man's education rather than his account at his banker's forming his passport into social circles. There exists a good understanding between the Danish medical profession and the general public. One very seldom hears of a medical man being judicially accused of faults in treatment, and a fine in such cases is almost unknown. Such a thing would be ruin to any practitioner, as his case would soon be public property in a small country like Denmark. There is, too, a decidedly good feeling among the members of the profession themselves, at least in Copenhagen. There are, however, very few medical societies and clubs, partly owing to the fact that clubs do not flourish in this country, and partly because medical men, being chiefly practitioners, have very little time to spend outside their homes. This is also the reason why there are comparatively few Danish medical authors."

A Fine Opening.—The following instructive announcement appeared in the columns of the *Wiener Medicinische Zeitung*. It may throw some light on the Austrian social system: "To Physicians: A young single medical doctor, who by means of matrimony, and the assuming of an important and lucrative dental practice, is inclined to found a very agreeable existence, is hereby given an opportunity. A yearly income of 10,000 guldens can be shown. The young lady concerned is the daughter of very respectable parents, seventeen years of age, beautiful, well-bred, and correspondingly educated. The father wishes to retire from business, and will deliver to the young doctor a dental practice, dwelling beautifully furnished, together with material, dental tools, and instruments to the value of 8,000 or 10,000 guldens entirely gratis. Dental knowledge is not necessary for the beginning, since this can be acquired in the course of a few months, under the instruction of the present possessor. Applicants address 'Zahnarzt,' care Editor *Allgem. Wiener Med. Zeitung*."

Cremation and Burial in London.—Cremation is regarded with but little favor by the London official mind. Two furnaces have already been built under the auspices of the Cremation Society, and as Mr. Justice Stephen has declared from the bench that the practice is not illegal, more are shortly to be constructed. But at South Kensington the cremationists have been refused a stall at the forthcoming Health Exhibition. The chairman of the Health Committee does not approve of it. May we live to see him cremated! (after death), says the *Pall Mall Gazette*. The latest reverse sustained by the votaries of "ashes" is the decisive negative given by Parliament to the Cremation bill. This bill proposed to regulate cremation and place it under proper restrictions, but the second reading was negatived by nearly two to one. Our present method of burial is insanitary in the manner usually adopted. Many of our metropolitan cemeteries are in the centre of crowded districts—even those of modern creation. Brompton Cemetery, for instance, is now surrounded by houses on all sides, and is the centre of a densely populated district. It needs no very lively imagination to picture the possible—nay, probable—effect upon the dwellers in the vicinity. It has been shown, too, by some very loathsome practical experiments, that under certain conditions the human body is not completely disintegrated and resolved into dust for a good many decades. About five or six years ago a very ancient city burying-ground, Bunhill Fields, the place where John Bunyan lies interred, was sold (!) to a well-known firm of London carriers, who obtained permission to build stables over it and remove such bodies as they found necessary, they engaging to re-inter them elsewhere. In sinking the piles whereon to erect their buildings, they came across and removed a large number of corpses. Decomposition had, of course, commenced, and the effluvia was overpowering, but some bodies were scarcely disintegrated at all and presented an almost fresh appearance. A large number of bodies were carried away as dug up; they were carried on men's backs, who were plied with brandy *ad libitum*. The details may be mentally realized without much description, and the danger to health is obvious. This affair was hushed up as much as possible, and I believe no notice of it appeared in the public press at the time. I have known other instances of graveyards being disturbed, to the danger of the living and the desecration of the dead. It is not long since it was proposed to asphalt over an East-end disused graveyard and then build on it. Nearly all our large railway lines run through one or more churchyards, and many public buildings in London have been literally founded on the tombs of our ancestors. The National Gallery is one. Some of these evils would doubtless be removed if "burning" became common, but it is plain that even from a scientific point of view it is not quite free from objection. It hides all trace of poison and other modes of violent death, and renders a subsequent "exhumation" impossible. It is legal now, and it is thus a pity the bill restricting its practice did not pass.

Treatment of Angeiomatous Growths.—Dr. H. O. Marcy writes in the *Archives of Pediatrics* for May, 1884, describing a method used by him for the removal of nævi. He states that he has for a considerable time employed in the treatment of a variety of vascular growths a suture which he calls "the shoemaker's stitch." The eye of the needle is placed near the point which is without cutting edges. Armed with the ligature the needle, which is set in a strong handle, is thrust deeply under and quite away from the vascular growth; emerged from the distal side the ligature is detached and the opposite end threaded, when it is withdrawn and again inserted purposely only a short distance from the first puncture, since it is important to include only a comparatively small portion of tissue. Thus the process is repeated, stitch after stitch, until the entire mass is enclosed and the fixation is completed by a single knot. In this way uniform and steady pressure can be attained and maintained as long as is desired. The purpose of the procedure is not to strangulate and cause necrosis of the tissue, but to constrict so as to reduce to the minimum the circulation and yet preserve its integrity. The author claims by this method the avoidance of the unsightly cicatrices sometimes resulting from the cure of angeiomatous growths.

SOME REMARKS ON AFFECTIONS OF THE HEART.

BY J. MILNER FOTHERGILL, M.D. EDIN., HON. M.D. RUSH MED. COLL., ILL.

ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

II.

VALVULITIS.

THE ordinary impression about valvular disease of the heart is that it is a morbid action which, once set on foot, marches steadily and resistlessly onward, the valve mischief getting worse and worse and consequently making further and further demands for compensatory hypertrophy until the system fails to meet the demand, and then the patient dies; and, what is more, that this is a comparatively speedy affair. Such possibly is correct from the point of view of the dead-house, and is borne out by my remembrance of the Pathological Institute of Vienna, but is very far from what experience of practice in England tells me. That such cases do occur from time to time may not be denied, and a marked instance came under my notice rather more than a year ago. The patient was an athletic man, about thirty, of good family history, who was playing cricket in September, 1882, and who died with valvular disease, both aortic and mitral, the latter the more pronounced, and effusion into every serous cavity, in the middle of January, 1883. Here the progress was terribly swift. I can also remember a case in my father's practice, where rheumatic fever was followed by mitral disease, and the patient, an elderly man, died with dropsy in about eighteen months from his first being taken ill. But I unhesitatingly deny that such cases are the rule, or even common; in fact, they are rare—in my experience.

This, indeed, is valvulitis as seen in the dead-house, and spoken of by pathologists; but it is not the valvulitis of those who live, crippled indeed, but still alive and often at work. The prognosis of valvular disease is very different now from what it was held to be among earlier observers. That cases running their course swiftly made the deepest impression on these pioneers is comprehensible enough. But there is, I rejoice to say, another side to the question, and that side will now be presented to the reader.

There are two forms of valvulitis which must be clearly differentiated from each other in order to comprehend the subject properly. There is (1) acute valvulitis; and (2) chronic valvulitis.

(1) *Acute valvulitis.*—This may be the result of rheumatic fever, to a lesser extent of scarlatina or other malady of early life, or it may be set up by violent effort, or be possibly rheumatic.

Here there is an inflammatory storm which passes over the serous lining of the interior of the heart. Beneath this inflamed serous membrane there is a development of connective-tissue corpuscles into the structures underneath the endocardium. In the valve-curtains, in the chordæ tendinæ, in the musculi papillares, there is a growth of soft young cells. The inflammatory storm passes away, but the soft young cells remain; and possessing, as they do, an inherent tendency to contract in no long time, they shrivel up, and then distortion and mutilation of the parts in which they exist follows. The valve-curtains are shrivelled, may be dragged down to the stumps of the musculi papillares by contraction of the tendinous cords; or they are fused together, and the mitral valve is converted into a fleshy cone with a perforation down it, extending into the left ventricle. Such is the ruin wrought in the mitral valve by this deforming process. In the aortic cusps there is shrivelling of the free edges, one or more being mutilated, and that more or less severely as the case may be. But once the mischief done, it remains, like the cicatrix of a burn, static and non-progressive. A certain damage is done to the valve-curtains which cannot be undone, and which, as we saw in the preceding article, is compensated (so far as the powers of the system will permit) by a proportionate growth of the wall of the muscular chamber behind the lesion.

This is valvular disease of the heart, as it has presented itself clinically in my experience. As a malady of childhood it is infinitely commoner in little girls than little boys. Some die of dropsy about puberty, others live on. In one instance I have personally watched the case from about the age of eight till the girl is now twenty-six years old, a village schoolmistress, who gets through her duties without discomfort, but is short of breath on effort, as dancing, and who, when out of health, is apt to have some œdema about her ankles. In another case a peasant had rheumatic fever under my father, with mitral regurgitation, about twenty-eight years ago. He suffered at times from severe pulmonary congestion and spat blood, and was once, indeed, gravely ill under my care eighteen years ago. At that time he had to work for a living, but, fortunately for him, he got some money left him, which enabled him to live without toil, and since then he has never been seriously ill, only scant of breath. He is a hale, cheerful old man. He writes me at the present time: "I don't think I suffer so much from my heart as I did some years ago, but my breathing don't improve with old age." In a third case, that of a well-known authoress, she made severe efforts about fourteen years ago which resulted in acute valvulitis, leaving behind it a distinct mitral regurgitation, which makes itself felt only on effort. While she is at her desk she is well. She is married and has had children, but her literary work goes on.

So much for mitral cases. A distinguished artist has had aortic regurgitation for ten years. The lesion is a moderate one and the ventricular enlargement is not immense; he leads a quiet life, and is not measurably worse during the last six years. Some time ago a patient came to me for a malady in no way connected with his heart, who had distinct aortic regurgitation. It was a small lesion, the hypertrophy was not great, and he had worked hard as a solicitor all the time since it was set on foot, seventeen years previously. A doctor-patient of mine had a considerable aortic regurgitation, dating back to the time when he was a medical student under the famous Stokes, of Dublin, and who for over thirty years had worked hard in practice—often, indeed, being at death's door—but in whom the valve lesion was as static as the Dead Sea. Such are some of the aortic cases which have come under my notice. Of aortic obstructions it is unnecessary to speak; they very commonly run on for years, into the teens, indeed, in several cases known to me. This is the other side of the question—the clinical as compared to the dead-house aspect!

(2) *Chronic valvulitis.*—This is a totally different malady. It is a slow progressive disease as a rule, sometimes not very slow. It is otherwise known as sclerosing endocarditis. It consists of a parenchymatous inflammation, or cell-growth into the valve-curtains, and earthy salts may be deposited in the neoplasm when the condition spoken of as ossification of the valves is found. At other times atheromatous tubercles are found springing from the surface of the affected valves. Here there is, speaking broadly, usually an hypertrophied ventricle and hard arteries, with firm, incompressible pulse and a loud aortic second sound. In other words there is "the gouty heart." There is a high blood-pressure in the arteries, the ventricle overcomes this by hypertrophic growth, and by the powerful contraction of the ventricle the mitral valves are closed violently and so become chronically inflamed, or the aortic cusps undergo strain from the powerful aortic recoil, and a cell-growth is instituted in them. This form of valvulitis is essentially progressive, though the rate of progress is by no means the same in each case. The muscular changes which have preceded the valvulitis must be entertained in these cases, as well as what may have followed. A number of such cases have passed under my observation, from the pre-murmuric stage of accentuation of the aortic second sound to the gradual development of an unmistakable murmur, and the other evidences of a valvular lesion. In one case death followed within eighteen months of the time when no murmur was to be heard, and was due to aortic valvulitis. The course is usually not so swift. For four or five years a number of such cases have been under observation, but all are marching to the grave at a measurable rate. Mitral valvulitis in the gouty heart does not, I am inclined to think, progress so quickly as is the case with aortic valvulitis, at least usually. In one case, an old medical man over ninety, there was mitral stenosis which ran a course of about three years, so far as is known, accompanied by severe angina pectoris.

There is, then, a totally different prognosis, as there is a totally different pathological action at work, in cases of progressive valvulitis to what there is with the static injury left by an acute endocardial inflammation. And it is therefore a matter of the greatest moment to discriminate which affection it is before one in any given case.

Then there is true gouty inflammation of the valves of the heart, well described long ago by James Wardrop. This is usually the progressive valvulitis just described, but cases do crop up where the process is rather that of the acute articular gout followed by a period of quiescence. Of this last I have not had sufficient experience to speak very confidently.

Of ulcerative endocarditis my experience is limited. There is a persistent high temperature with the development of a murmur ; and the case runs its course with painful celerity.

These two last forms will be put aside in the following remarks, which are confined to the usual forms of valvulitis commonly encountered in practice, viz.: the static injury, and the progressive or sclerosing valvulitis.

Having determined from the murmur the seat of the valvular lesion, according to the rules laid down in our text-books, it is not well, in my opinion, to assume straight away that you have to deal with a progressing valvulitis which will soon exhaust the power of the organism to keep pace with it by compensatory hypertrophy of the muscular tissue. That such is at times the case is indisputable. Having decided that there is a real lesion there are some other points to be ascertained.

The first is the character of the valvular mischief; whether the case is one of by-past injury without any tendency to progress, or is of the progressive type. This the history of the case will usually determine. If the patient has been scant of breath on exertion for years, then probably the lesion is old. Perhaps the dyspnœa on effort dates from some comparatively recent illness, may be rheumatic fever ; or if an elderly person with a mitral lesion, from an attack of bronchitis. If, however, on the other hand, the patient complains that recently the breath has been found to be getting short, and the murmur has got the wonted concomitants of the gouty heart, probably the mischief is a progressive valvulitis. Not only your prognosis, but your treatment will be materially influenced by the character of the lesion.

The second is its extent. Have you a large or a small lesion to deal with ? The amount of injury inflicted varies with different cases. A mitral lesion may be so small as only to make itself felt on considerable effort ; or it may be such as to necessitate a light occupation ; or it may be so great that the individual is reduced to the condition of a human lizard, incapable of active movement. Such a case I have in the hospital at present in a girl of fourteen. Her injected cheeks, her blue lips, her hurried respiration alike tell of a large mitral lesion. The congestion of the pulmonic circulation, the diminution of the thoracic space, and consequently the necessity for rapid inspiration, tell far more as to the extent of a mitral lesion than does the character of the murmur. Eloquent as to the presence of mischief, the murmur is voiceless as to its extent. That must be measured by other evidence than that furnished by the stethoscope. Then there is the associated condition of the muscular wall. A small lesion (no matter whether its murmur be small or loud) only calls for moderate hypertrophy ; and if in aortic regurgitation you find little (that is, comparatively little) ventricular enlargement you may feel pretty certain you have only a small lesion before you. That small lesion may become a large one ; and, if so, the enlargement of the ventricle will tell you very distinctly of the progress of the valvulitis, and the amount of deformity it is producing. The aortic valvulitis due to strain progresses at a very different rate in the university oarsman, who gives up his athletics and settles down as a parish priest, married and sedate, to that exhibited in the case of a boatman who must work hard to live. Where strain is continuously thrown upon the parts, the progress from bad to worse is rapid. Where a quiet life is led, the valvulitis seems to come to a standstill. As a broad rule, then, it may be laid down that in aortic disease the size of the left ventricle is the best guide to the extent of the disease. And another broad rule may be laid down alongside this, viz.: the greater the enlargement the sooner the compensating hypertrophy will be exhausted ; the smaller the hypertrophy the longer it can be maintained. Consequently the prospects in a small lesion, if static, are infinitely better than in those cases where the lesion is a large one.

Beyond these matters lies the question of the condition of the muscular fibrillæ, whether well-fed, ill-fed, or the subjects of fatty degeneration.

When a patient presents himself or herself before a medical man, complaining of symptoms which point to a valvular lesion, and such is actually found, it does not necessarily follow that there is any marked change going on in the valvular mischief. This may be the case, but by no means necessarily so. The valve-injury may date back for years, but it is only recently that the patient has felt worse than usual. It is failure in the muscular wall ! There has been sustained over-demand upon the heart ; or there is a history of defective nutrition, or a mixture of both. Commonly it is found that the necessity for toil has made the patient persevere with it, disregarding the uncomfortable sensations until these last become supreme, and he must hie to the doctor. Or times have been bad, work slack, and wages small, and then the underfed condition reveals itself in loss of vigor in the restless, ever-working heart. Here it is enough to lessen the demand upon the heart, to provide a sufficiency of nutritive food, and brace up the heart-muscle by agents which increase the vigor of its contractions, and the case does well. The heart improves till its owner can once more work. Or maybe the digestion is upset, and the assimilation of al-

buminoids is defective, or their further elaboration by the liver is impaired by some disturbance of that viscus, and then the heart and diaphragm are alike underfed, and then the symptoms of fatty degeneration are closely simulated. And such is the explanation of many a sudden breakdown in a heart, the seat of an old-standing, non progressive valvular lesion. Here attention to the liver is requisite for sufficient tissue-nutrition. In other cases there are not merely the symptoms of fatty degeneration, but other evidences of tissue-decay are furnished (a matter which will be considered in the next article), and there exists no reasonable doubt that mural decay is on foot, resistless and irremediable. When assured that such is the case, no prognosis can be too dark.

In dealing with a valvular lesion there are to be considered (1) its site; (2) its pathological nature; (3) its extent; and (4) the associated condition of the muscular walls; not only diagnostically but prognostically and therapeutically.

What lessons in practice does pathology teach us as to the treatment of valvulitis? It tells us that while the inflammatory storm is sweeping over the endocardium the most perfect rest is desirable. Yes; but its study tells us more! It tells us that so long as there is any cell-growth going on underneath that endocardium, perfect rest should be maintained. The less the development of the connective-tissue corpuscles, the smaller the ultimate deformity caused by their inevitable contraction. To limit the cell-growth is to bound the resultant lesion. So clear is this, that no roll of statistics is required to prove it. Perfect rest in the recumbent posture, the system calmed, and the blood-pressure lowered by chloral if necessary.

Such is the rational treatment of a case of acute valvulitis until there is a reasonable assurance that the day of the development of connective-tissue corpuscles is past and over. Limit the lesion first! When the injury is done, the process of mutilation over, then, and not till then, please, comes the time to help the system to build up the necessary compensatory hypertrophy. The first line has to be inexorably maintained until the valvulitis is or has been brought to a standstill. To get a patient who has been the victim of endocardial inflammation to make one unnecessary effort, is to drive a nail into his coffin. In progressive valvulitis quiet is desirable so as to avoid strain on the diseased valves. In both cases digitalis, which increases the strain on the valves, is contra-indicated in the true interests of the patient until heart-failure sets in. When a gouty element is present in chronic valvulitis, then a non-nitrogenous dietary and uric-acid solvents are distinctly indicated.

Virchow upon the Cholera and Tubercle Bacillus.—At the time of the return to Berlin and public reception of the Cholera Commission, Professor Virchow made a speech, in which he uttered some timely words of warning. He said: "It appears to me that the Government is not entirely free from the opinion that with the discovery of the bacillus everything is accomplished which may be necessary to control the disease. In this connection I may speak a warning word. It is more than thirty years since we discovered the little organism which causes the small-pox, but this fact has not changed in the least the practical measures previously adopted for its prevention. The tubercle bacillus is a very important thing, but with the exception of a new point of view of the disease, which is given, we are no further advanced in our practical relations to it." He then goes on to say that the cholera has for some time been practically treated as though it were caused by a special organism. He also referred to the laxity of the English in the matter of quarantine.

Hiccough.—A sure cure for hiccough is a pinch of snuff, according to Dr. P. F. Ellis, in the Texas *Courier-Record*.

MANACA IN THE TREATMENT OF RHEUMATISM.

Report of Fourteen Cases.

By C. M. CAULDWELL, M.D.,

visiting physician to st. joseph's hospital, new york.

During the past year I have used the fluid extract of manaca in the treatment of thirty-five cases of rheumatism, and have come to regard it as a valuable remedy in certain forms of this disease. The drug was first brought to my notice by Dr. John H. Ripley, who had prescribed it, in private practice, with very satisfactory results.

As the information to be gathered concerning the action of the drug was rather indefinite, it was decided to note its effect upon persons in health, before commencing its use in disease. Accordingly, two healthy men were given twenty drops of the fluid extract, five times daily for one week. The only appreciable effect was an increase in appetite and a slight "valerian-like" odor of the urine; otherwise this secretion remained unchanged. The pulse and temperature were unaffected, and no abnormal sensations were produced.

The drug was now prescribed for patients suffering with various forms of rheumatism. My cases differed widely in occupation, habits, and social position—some being private patients, some inmates of St. Joseph's Hospital, while others were treated at the New York Polyclinic. The ages ranged between eleven and fifty-eight years. The sexes were about equally represented. The dose of the fluid extract—which was that prepared by Parke, Davis & Co.—was from half a drachm to three drachms a day. In no case did the drug disturb the digestion, while in several instances the tongue cleared and the appetite improved during its administration. In about one-eighth of the cases frontal headache or a sense of fulness in the head developed after the medicine had been pushed for several days.

Manaca was used in but two cases of acute articular rheumatism with high temperature; in both it absolutely failed to relieve the pain or modify the fever.

In cases of chronic rheumatism it frequently gave relief, and in a few instances all rheumatic symptoms slowly disappeared. In this class of patients my results would probably have been better had the dose been larger, as Dr. W. S. Gottheil reports (in The Medical Record of September 8, 1883) seven successes out of twelve chronic cases, all having been treated with large doses of the drug. The doctor usually gave six drachms of the fluid extract per day, and occasionally as much as an ounce and a half in twenty-four hours.

By far the most satisfactory results, in my experience, were obtained in cases of subacute rheumatism, in which there was little or no rise in temperature. Fourteen patients suffering with this form of the disease were treated. Twelve recovered and two received no benefit whatever.

The following are histories of the cases of this class:

Case I. *Rheumatism of six weeks' duration; recovery in one week; two relapses.*—R. J——, twenty-one years of age, plumber, applied for treatment February 12th, stating that for six weeks he had been unable to work on account of rheumatism in all the larger joints. This was his first attack of the disease. The knees were the original joints involved, but the pain and swelling had constantly shifted from one articulation to another, at the same time increasing in severity, so that now it was difficult for him to walk even a short distance. Examination showed moderate redness, swelling and tenderness of the ankles, left knee, and right elbow. The patient's general condition was excellent. Temperature, 100⅘°. No cardiac complication present. Manaca given in twenty-drop doses four times a day.

February 14th.—Considerable improvement has taken place. Both swelling and redness are rapidly diminishing. Continue treatment.

February 19th.—The patient expresses himself as perfectly well, being entirely free from rheumatic symptoms. Ordered to continue manaca in connection with tincture of iron for ten days longer.

February 28th.—Patient returns, complaining of the same trouble, which came on yesterday while working in a newly plastered room. His ankles and left knee are red, hot, and swollen. He has taken no medicine since last seen, as he considered it unnecessary "to drug himself when he was well." Manaca ordered as before.

March 5th.—All symptoms have again subsided, and the patient is at work. He refuses to continue treatment, as he holds that "medicine is for the sick, not the well."

April 2d.—He has remained in perfect health up to two days ago, when the old enemy again attacked the ankles and knees. These joints are swollen and tender to-day. Manaca as formerly.

April 4th.—Rheumatism has subsided, and the young man is now willing to continue any medicine prescribed. Manaca and iron tincture are to be kept up for two weeks.

May 1st.—There has been no further relapse.

Case II. *Rheumatism of thirty-six hours' duration; recovery in one week.*—R. E. C——, aged thirty-three; actress. Patient was first seen February 11th, and had then been in bed for thirty-six hours, suffering with an attack of rheumatism, which had involved in rapid succession the left shoulder, elbow, both wrists and ankles. The joints of the upper extremities were swollen, hot, and exceedingly tender. Temperature, 101°. The patient was thin, anæmic, and in very poor general condition. Considerable cardiac hypertrophy and a well-marked mitral regurgitant murmur were noted. Thirteen years before she had "rheumatic fever with rheumatism of the heart," confining her to bed for about two months. Since had often had mild attacks of the articular affection. Cardiac palpitation had at times been troublesome. A saline laxative, to be followed by twenty drops of manaca, five times daily, was ordered, and the affected joints wrapped in cotton.

February 14th.—The patient has been very comfortable for twenty-four hours, and rheumatic symptoms are rapidly subsiding. The temperature is normal. Treatment continued.

February 18th.—Recovery is complete. Manaca and iron tincture are to be continued for two weeks.

March 15th.—There has been no relapse.

Case III. *Rheumatism of three weeks' standing; recovery within a week; relapse.*—M. W——, aged twenty-five; porter. Patient came under observation February 19th. He had then been unable to attend to business for three weeks on account of rheumatic pains and stiffness in knees, elbows, ankles, and wrists. For two days the right knee had been red, swollen, and somewhat tender; a week previous the elbows were in the same condition; and before that the right ankle had been the troublesome joint. His general condition was fair. Temperature normal. He never had rheumatism before, but both parents suffered from the disease. Ordered manaca, in fifteen-drop doses, five times daily.

February 25th.—All his symptoms have subsided and he is at work. Is to continue treatment one week.

March 2d.—Patient returns with his former complaint in both ankles and left wrist. He neglected taking his medicine as directed, thinking the precaution unnecessary. Last evening, after exposure, the present attack came on. Manaca as before.

March 5th.—Patient is in good condition once more. Ordered to continue medicine for ten days, and then gradually diminish the dose.

Case IV. *Rheumatism of five weeks' duration; recovery in five days.*—M. S——, aged thirty-five; domestic. This servant was first seen on February 21st, having then had rheumatism for five weeks. It had shifted from one articulation to another, until nearly every joint had, in turn, been stiff and painful, but never inflamed. In spite of the usual anti-rheumatic remedies she had not improved. Four or five years before she had a similar attack. Her general condition was excellent. Manaca in fifteen-drop doses, four times daily, was ordered.

February 23d.—Considerable improvement has taken place already. Continue treatment.

February 26th.—Reports entirely free from rheumatism and feeling very well. Ordered to continue medicine one week longer.

Case V. *Rheumatism of six weeks' duration; recovery in ten days.*—E. O'C——, aged forty-nine, housekeeper. The patient was first seen February 26th, having then been suffering for six weeks with subacute rheumatism involving the knees, elbows, and wrists. For about two months she had had more or less supraorbital neuralgia and been greatly troubled with acid dyspepsia. For three years she has been subject to subacute rheumatic attacks. Her general condition was fair, but anorexia and insomnia were complained of. The knees and elbows were stiff and tender, but no swelling was present. A saline laxative, followed by twenty drops of manaca four times daily, was ordered.

February 28th.—No improvement in the condition of joints. Appetite and digestion are a little better. Continue treatment.

March 2d.—Joints are much better, but the patient complains bitterly of lumbago, which came on as the joints began to improve. Continue manaca, and apply sinapisms over the lumbar region.

March 6th.—Reports free from both lumbago and rheumatism to-day. Is put upon full doses of iron tincture, to be continued for one month.

April 15th.—The patient was looked up to-day. She has had no return of her former troubles, but keeps a supply of manaca on hand for immediate use in case of returning rheumatic twinges. She is also treating several of her rheumatic friends with the remedy.

Case VI. *Rheumatism of two days' standing; recovery in four days.*—C. E. K——, aged thirty-two, cutter. The patient was being treated for phthisis when, upon February 28th, he was attacked with pain, tenderness, and stiffness in both shoulders. Within twelve hours these symptoms shifted from the right shoulder to the elbow and wrist. As his lung trouble was progressing favorably it was decided not to interrupt the antiphthisical treatment, and a stimulating liniment only was ordered for the affected joints.

March 2d.—The rheumatism is worse. Last night the patient was very restless from joint-pain. Give manaca in fifteen-drop doses every three hours. Stop all other medicines.

March 6th.—Rheumatism has steadily improved, and to-day is fairly gone. Stop manaca and return to former treatment.

March 31st.—There has been no return of rheumatism.

Case VII. *Rheumatism of two months' duration; recovery in one week.*—J. C——, aged twenty-three, engineer. Patient applied for relief February 28th, complaining of soreness and stiffness in the muscles of the lumbar region, also of well-marked lameness in both feet and ankles. The ankles, insteps, and toes were swollen and tender on pressure; slight redness but no heat was present. No other joints were involved. The young man had several previous attacks of lumbago, but never had articular rheumatism until two months before coming under observation. During those months his lameness gradually increased, although in fine weather he was able to get about quite well. His general health was good in spite of a free indulgence in tobacco and alcohol.

Total abstinence and fifteen drops of manaca five times daily were ordered.

March 3d.—Reported somewhat relieved of rheumatism, but suffering with a severe frontal headache, which

may be due to the medicine or to beer. He has taken both faithfully. Ordered a saline laxative and manaca as before.

March 7th.—Rheumatic and head symptoms have subsided and the patient has returned to work. Is to continue treatment for one week and report any relapse.

Case VIII. *Rheumatism of three weeks' duration; manaca a total failure.*—M. H——, aged thirty-five, domestic. For fifteen years this patient has had repeated attacks of pain and stiffness in all the larger joints, but always unaccompanied by inflammatory symptoms. During these attacks an approaching storm renders her almost helpless, while in fine weather she can do ordinary housework fairly well. Her habits were very bad. In fact she was intoxicated when first seen, and was suffering from gastro-intestinal catarrh, evidently due to a liberal use of beer and whiskey. She was free from rheumatism at the time. Treatment was directed against the gastro-intestinal disorder. Upon March 1st she began to complain of general joint-pain and stiffness, but as her stomach was still irritable it was not deemed best to institute anything in the way of internal anti-rheumatic treatment. The troublesome joints were rubbed with a stimulating liniment and covered with flannel.

March 13th.—The gastric trouble is much better, but no improvement in the rheumatism has taken place. Manaca in twenty-drop doses five times daily is ordered.

March 15th.—Pains are more troublesome. Rheumatism increasing in spite of improved general condition. Continue treatment.

March 19th.—No improvement. Continue treatment.

March 23d.—Rheumatic symptoms are decidedly worse. Stop manaca; try a mixture of potassium, iodide, and colchicum wine.

April 10th.—Patient made a very satisfactory recovery upon this treatment.

Case IX. *Rheumatism of four weeks' standing; recovery within two weeks.*—H. M. S——, aged forty-five, artist. The patient was first attended for rheumatism upon April 14th, and had then been troubled for about one month with aching and stiffness in all the larger joints. An approaching storm increased these symptoms so as to confine him to his room, while in fine weather he was out of doors, free from pain but never quite free from stiffness. In former years he had similar attacks, but of shorter duration. His appetite and general condition were poor. Pills of iron, quinine, and strychnine, with twenty drops of manaca four times daily, were prescribed.

April 17th.—Patient thinks he is a little better, but seems more stiff and feeble than at the last visit. Continue treatment.

April 21st.—Marked improvement has taken place during the last two days. Only trifling stiffness now remains. Same treatment.

May 1st.—Rheumatism has given no trouble for a week. Stop manaca and continue tonic pills.

May 15th.—No return of the disease up to date.

Case X. *Rheumatism of four days' duration; recovery in two days; relapse.*—T. McK——, aged forty-four, merchant. Patient had been under treatment for phthisical consolidation of the left apex for several weeks. Upon May 6th he was exposed during a profuse night-sweat, and the following day was confined to bed with pain and stiffness in all the larger joints, especially the knees. He had a similar attack years before. A mixture of potassium, iodide, and colchicum wine was ordered, and the limbs wrapped in flannel.

May 10th.—The rheumatism is no better, and the patient is troubled with anorexia and insomnia, being unable to take his usual exercise in the open air. Treatment changed to manaca, twenty drops six times daily.

May 12th.—Recovery from rheumatism is complete. Discontinue manaca and return to antiphthisical treatment.

May 16th.—A relapse occurred to-day, and patient is confined to bed. Manaca as before.

May 21st.—Recovery is again complete, and manaca is to be continued with other drugs for a couple of weeks.

June 20th.—No further relapse has occurred.

Case XI. *Rheumatism of two days' standing; recovery in six days.*—M. R——, fifty-two years of age, mason. When first seen upon June 15th the patient had been confined to bed for two days with his first attack of rheumatism. The knees, especially the right, were hot, swollen, and exceedingly painful on motion and pressure. The ankles, elbows, and wrists were also involved but less severely. Temperature normal. Appetite and general condition good. Wrap the joints in cotton and take twenty drops of manaca five times daily.

June 17th.—There is no change in the case except that the force of the inflammation is now felt in the shoulders and elbows, the knees being much better. Increase dose to thirty drops five times daily.

June 20th.—During the last two days recovery has been rapid, and the patient has spent most of his time out of doors. He complains of considerable frontal headache, which came on yesterday and is getting worse. Reduce dose of manaca one-half.

June 22d.—The patient has entirely recovered from rheumatism and headache. Stop manaca and take iron tincture for two weeks.

July 15th.—Patient seen to-day; has had no further rheumatic trouble.

Case XII. *Rheumatism of a day's duration; entire failure of manaca to relieve.*—C. J. S——, twenty years of age, salesman. Upon July 10th the patient, while under treatment for phthisis, fell asleep in a draught, and shortly afterward was seized with pain, heat, and swelling in the left shoulder and elbow-joints. In a few hours the inflammation shifted to the ankles, causing well-marked lameness. There was no rise in temperature. General condition was bad. Ordered manaca in twenty-drop doses five times daily.

July 12th.—The joints are more painful, and the patient more irritable than when last seen. Continue treatment.

July 15th.—The young man is steadily getting worse and is now confined to bed. Ordered the dose increased from twenty to thirty drops, but the patient refuses to continue the drug and intimates that he must have a change either of treatment or physician. He has a change of treatment, and a mixture containing potassium, iodide, and colchicum is given.

July 25th.—The patient has slowly but steadily improved since the last note was made, and is now almost free from rheumatism.

Case XIII. *Rheumatism of twenty-four hours' duration; recovery in two days.*—T. McG——, aged fifty-five, carpenter. For fifteen years this patient has been a sufferer from chronic rheumatism to a greater or less extent. When he came under observation he had had no rheumatic symptoms for six months, but had been much troubled by cardiac palpitation, cough, and dyspnœa. Examination showed extensive pulmonary emphysema, chronic bronchitis, and a mitral regurgitant murmur. His general condition was fair. Concentrated nourishment, rest, and a mixture containing convallaria and quebracho were prescribed.

Upon September 15th he awoke with stiff, swollen, and painful elbows, wrists, and ankles. During the day the knees became affected, and muscular rheumatism developed in the lumbar and cervical regions.

September 16th.—The condition remains as yesterday. All former medicine suspended, and manaca in twenty-drop doses five times daily is ordered.

September 18th.—The more acute symptoms have subsided, leaving only stiffness—especially of the knees. Iron tincture and convallaria are to be added to the manaca and continued for two weeks.

October 15th.—The above treatment has been carried out. No relapse has occurred.

Case XIV. *Rheumatism of two weeks' standing; recovery in five days.*—C. C——, aged eleven, school-girl. Was first seen, for rheumatism, upon September 22d. For several days she had complained of slight stiffness and soreness in the knees, shoulders, and neck. Her general condition was excellent. Ordered Dover's powder, to be followed by small doses of Rochelle salt three times daily.

October 1st.—The joint-stiffness and soreness has not entirely disappeared at any time since last note was made, and to-day it is worse than ever before. Ordered manaca in twenty-drop doses three times daily; also clothe the child in flannel undergarments.

October 3d.—Considerable improvement has taken place.

October 5th.—Recovery complete. Continue treatment for one week.

VERATRUM VIRIDE AND GELSEMIUM IN THE SUCCESSFUL TREATMENT OF TETANUS.

By R. B. HARRIS, M.D.,

SAVANNAH, GA.

The pathology of this most formidable malady is, to say the least of it, limited, and as yet wrapped in some obscurity. It is certain, however, that the symptoms of tetanus are to be referred to an unhealthy action in the nerve-centres, *spinal* and *ganglionic*. The disease has been thought by many writers to be a purely reflex phenomenon, and although the writer of this article is inclined to take this view of it, yet he is in considerable doubt as to its truth. In support of this theory cases of traumatic tetanus have been reported where, upon the division of the nerve, the spasms have ceased and the patient recovered.

Macnamara reports a case in which he saw tetanic spasms result from the ligation of a large bleeding pile, his patient being attacked with spasms of the sphincter ani muscle within thirty-six hours after the operation, and although the ligature was immediately removed, the disease ran a rapidly fatal course. Many cases of a similar character might be noticed here, but it is not the intention of the writer to discuss the pathology of tetanus in this paper to any lengthy extent. There are many cases of tetanic spasms coming under our observation where it is impossible to refer the attacks to a wound, abrasion, or apparent injury of any kind, and it is in these cases that the difficulty arises of attributing the disease to *reflex* action. The morbid effects in this class of cases may, however, be set up by some source of irritation in the mucous tissues or in the glandular system, and therefore hidden from view. The pathological changes in the spinal cord after death from tetanus are said to consist of extensive congestion of the tissues, with some exudations; but the question arises, and a grave one too, as to whether these changes are the *causes* or the *effects* of diseased nerve action; could this question be satisfactorily determined, much light would be thrown upon our subject.

It is unnecessary for the writer to enter upon the symptomatology of tetanus, except as to temperature; a bare mention of the fact, however, suffices, that all cases of this disease which have come under his observation have exhibited a temperature not exceeding 101° F., and this while the heart's action was as high as 130 and 140 beats to the minute. The main object of this article is to report four cases of tetanus treated by the writer, in which he believes recovery due to the administration of veratrum viride and gelsemium.

Case I.—W. S——, a young, vigorous, and plethoric man, twenty-two years of age. Was called to him August 11, 1867; found him with little or no fever, very restless and uneasy, tongue heavily coated, and speech a little thick. Upon inquiry, learned that two weeks since he had received a slight injury, from which he had suffered but little. Yesterday, the 10th, had a slight spasm which repeated itself this morning with some violence, and occasioned my being sent for in haste. After getting this much of the history of the case, I gave one grain of sulph. morphia and watched my patient closely. In about one hour or so I discovered some retraction about the scrobiculus which caused a slight difficulty of breathing. I now began to suspect tetanus, and, fearing this uneasiness about the epigastrium portended another spasm, I gave him a teaspoonful of laudanum. (This case came under my treatment before the hypodermic syringe was generally used.) I examined the wound he had received, and found nothing but the cicatrix of what appeared to have been scarcely more than a scratch, just above the patella of the right knee. His bowels had not been moved for two or three days, I therefore had administered two ounces castor oil and twenty grains calomel in combination. I now noticed considerable contraction of the extensors of the back, and some rigidity of the entire muscular system; gave two grains of gum opii, and in a short time, seeing that a spasm was inevitable, gave a teaspoonful of laudanum with the hope of keeping it off; but in half an hour after this last dose he was attacked with a most severe spasm, his body forming a complete arch, and lasting ten or fifteen minutes. As soon as this was over I gave him two more teaspoonfuls of laudanum, which I got down with some difficulty; in a few minutes he again had a most terrible spasm. The muscular system was now perfectly rigid, the jaws firmly closed, and the hands tightly clenched, and this after the administration of four teaspoonfuls of laudanum, two grains of opium, and one grain of morphia in four hours. The pulse now ran up to 110, and somewhat irregular. Had the spine and extremities vigorously rubbed with turpentine and mustard, and enemas of salt, soap, and warm water given, but without the desired effect. Spasms continued at short intervals.

August 12th.—This morning patient perfectly rigid, pulse 140, and pupils very much contracted. The temperature in this case was not taken for want of a thermometer. Having given all the *narcotics* I thought was prudent, I determined to change my tactics, and accordingly gave patient ten drops Norwood's tinc. veratrum viride, and having had his head and shoulders pulled over the edge of the bed with a large tub underneath, I poured four large pitcherfuls of cold water over the head, neck, and shoulders; when the last pitcherful was being poured on the system gradually relaxed, and my patient in a few minutes lay seemingly exhausted; pulse now 130; pupils contracted. Two hours and a half after the first dose of veratrum I gave twelve drops more. At three o'clock, now three hours since the last dose of veratrum was given, I gave another of twelve drops; in one hour his pulse dropped to 104, and he fell asleep.

At 6 P.M. another violent spasm came on, and I again resorted to the cold douche with equally good results as before, and as soon as the spasm ceased I gave another dose of veratrum combined with fifteen drops tinc. gelsemii. (Tinc. gelsemii was made of the green root, four ounces to a pint of ninety-five per cent. alcohol, macerated for fifteen days and filtered; the tincture made from the dried root is almost worthless.) In two hours after this dose was taken the pulse fell to 68. Patient now perfectly quiet and seems much better, pupils almost natural size.

Under this condition of things, I ordered four drops of veratrum (Norwood's) and eight of gelsemium to be repeated every four hours, with instructions that, should a spasm come on, the cold water was to be used as before.

August 13th.—This morning patient seems much better; pulse 64, skin cool, pupils dilated, but tongue very heavily coated; ordered an enema of castor oil and warm water, which brought about a very copious action of the

bowels. Discontinued the veratrum and gelsemium and ordered quinia sulphate, three grains every three hours. Was sent for this evening, and on arrival I found my patient in another violent spasm. I at once applied the cold douche as above mentioned, and as soon as possible administered ten drops of veratrum and fifteen of gelsemium; in a short time the muscular system became relaxed and patient more quiet. After waiting two hours I repeated the last-mentioned dose, and in a short time after had the satisfaction of witnessing the gradual fall of the pulse from 120 down to 68 beats. I now ordered veratrum and gelsemium to be repeated and continued in four and eight drop doses every four hours until my return.

August 14th.—Patient doing well, but a little dull; continued last prescription; pulse 60; ordered a flight milk punch three times a day.

August 15th.—To-day patient is brighter and calls for nourishment; pulse 62, pupils natural, and tongue cleaning; takes his nourishment readily, but complains of great stiffness of the jaws; continue prescription as above.

August 20th.—I have attempted to stop the veratrum and gelsemium twice since the 15th, but each time my patient evinced some spasmodic symptoms, and I returned to them in combination as before, with positive results.

August 23d.—Patient improving slowly, is very much prostrated, but has an increasing appetite. Veratrum and gelsemium continued in three- and five-drop doses every four hours with quinine.

August 26th.—Patient discharged to-day, with instructions to continue the medicine for five days longer, gradually diminishing the dose.

Case II.—This case came under my observation June 18, 1879, and was a case of idiopathic tetanus in a girl twenty years of age. When I first saw her she was in a most violent spasm, no portion of her body touching the bed on which she was lying, except her heels and the back of her head. I immediately resorted to the cold douche, but without the same happy result as in the preceding case; the effect was good, however, and I soon had an opportunity of giving fifteen grains of calomel and two ounces of castor oil in combination. Tongue very much coated; pulse, 126; temperature, 99½; respiration, 23. Ordered the following to be given at once:

℞. Fl. ext. veratrum vir..... 3 j.
Fl. ext. gelsemii..... 3 iij.
M. S.—Give fifteen drops in a little water every two hours, and increase each dose two drops.

Saw her again in four hours from my first visit; had had two spasms; pulse, 112; continue prescription. Four hours from *last* visit, no more spasm, pulse down to 40; gave a tablespoonful of brandy, shortly after which the pulse rose to 70. Continue prescription in ten-drop doses every four hours. This patient was up in seven days, but continued my prescription for one week, gradually diminishing the dose.

Case III.—Negro boy, aged eleven years; was called to him December 14, 1881. Upon inquiring into the history of the case, I learned that about two weeks prior to this time he had received a severe blow upon the back; on examination there was no external signs of violence, except that there was an apparent tenderness about the third and fourth dorsal vertebræ. The boy was speechless; pulse, as well as I could count it, between 140 and 150; temperature (in axilla), 100°; jaws so firmly closed that I could scarcely insert the point of the blade of a thin case-knife between the teeth, and a terrible rigidity of the entire muscular system. In this case I saw no hope of recovery, but in a few minutes I had a course of treatment laid out for him, and lost no time in putting it into execution. I had a large tub of hot water brought in, and emptied a common size (quarter-pound) box of mustard, and a half-pint of salt into it, and put my boy in up to his neck; while he was in this bath I had another smaller tub of *boiling* water brought in, and into this I put a large blanket; I now gave my patient five drops of the fluid extract of gelsemii and half a drop of the fluid extract of veratrum viride hypodermically. After being in the bath twenty minutes I had the blanket in the boiling water wrung out and spread upon his bed, and the boy immediately rolled in it up to his chin, and in an hour after repeated my hypodermic dose. Some discretion should be exercised in rolling a patient in this blanket taken immediately from a tub of boiling water, as there is danger of too much heat. Having to go to another patient I returned in two hours, feeling that I would not be surprised to find him dead; but to my astonishment he was as limp as an old wet rag, and in a profuse perspiration; pulse 98, but jaws still firmly closed. I ordered castor oil and warm water enemas to be given every fifteen minutes, until an action was had on his bowels. Saw him again about bedtime, six hours from my last visit; bowels well acted on; pulse, 104; gave him another hypodermic dose of veratrum and gelsemii and rolled him in another hot blanket as before. I could now get the point of a teaspoon between his teeth. Ordered the following:

℞. Fl. ext. veratrum vir..... 3 j.
Fl. ext. gelsemii..... 3 iij.
M. S.—Give ten drops in a little water every four hours.

December 15th.—Patient improved in every respect; pulse, 84; temperature, 99°. When spoken to he answers with a nod or shake of the head; has taken some nourishment. Ordered last prescription continued, with the addition of three grains of quinine every four hours.

This case progressed to almost complete recovery, was up and walking about the house, when suddenly, from some unknown cause, he was attacked with convulsions and died before medical aid could be obtained, on December 25th.

Case IV.—J. M——, aged fourteen years; about three weeks since, this boy received an injury on the side of the head, caused by a blow which had cut to the skull. His father told me that about two weeks after the reception of the injury, he had noticed that the patient got about very badly and would occasionally fall down.

I was called to this case on February 26, 1884; found him sitting up, but having regular tetanic spasms every few minutes; pulse, 120; temperature very little above normal; jaws partially closed and rigid. I at once gave him an ounce and a half of castor oil and twelve grains of calomel in combination, and ordered him to bed, giving his mother instructions to keep warm poultices to the wound on his head.

February 27th.—Patient in the same condition as when I saw him yesterday, except that his bowels have been copiously acted on by the calomel and oil. Ordered the following:

℞. Fl. ext. veratrum vir..... 3 j.
Fl. ext. gelsemii..... 3 iij.
M. S.—Give fifteen drops in a little water every three hours.

This evening (February 27th), pulse down to 48; gave him a little brandy and ordered prescription to be continued in eight drop doses every four hours, with the addition of three grains quinine with each dose. Whenever my patient was sleepless at night I occasionally gave a few grains of chloral hydrate and bromide of potassium, but with this exception, there was no other treatment instituted in this case, which progressed to complete recovery in fourteen days.

I am somewhat in doubt as to the therapeutical action of the veratrum and gelsemii, but will have more to say upon the subject in the near future. In the meantime I earnestly ask the profession to give this matter their serious consideration and attention, and report the results.

WHEN ARE WE AT GREATEST RISK FROM CONSUMPTION?

By EDGAR HOLDEN, M.D., Ph.D.,
MEDICAL DIRECTOR, MUTUAL BENEFIT LIFE INSURANCE CO.,
NEWARK, N. J.

For many years, even among the best informed, the impression has prevailed that consumption exhibits a preference as regards development, for certain ages. Thus, it has been the conviction that those who escape the marasmus and tubercular meningitis of infancy come again into danger at puberty, and that again between thirty-two and thirty-eight a climacteric is reached at which the mortality acquires its maximum of intensity, then diminishing to declare a wholesale sweep between sixty and sixty-five.

These views have grown out of an experience apparently well founded, since the mortality in every physician's personal field of observation has seemed to be greatest at those periods, but the conclusion is nevertheless a fallacy, and it has been made broader and deeper by statistics of mortality in which the ratio of deaths from consumption to the total number of deaths has been relied upon.

A moment's reflection, however, will show that while we may judge of mortality from any given disease with reasonable accuracy by comparing the number of deaths with the total number of deaths; yet, for individual ages or decades, we must obtain the ratio of deaths borne at these ages to the total number *living* at those ages.

The reason for this will be obvious from the fact that a far greater number are living between thirty and forty than between fifty and sixty, and consequently there is a far greater harvest for this most prevalent of diseases.

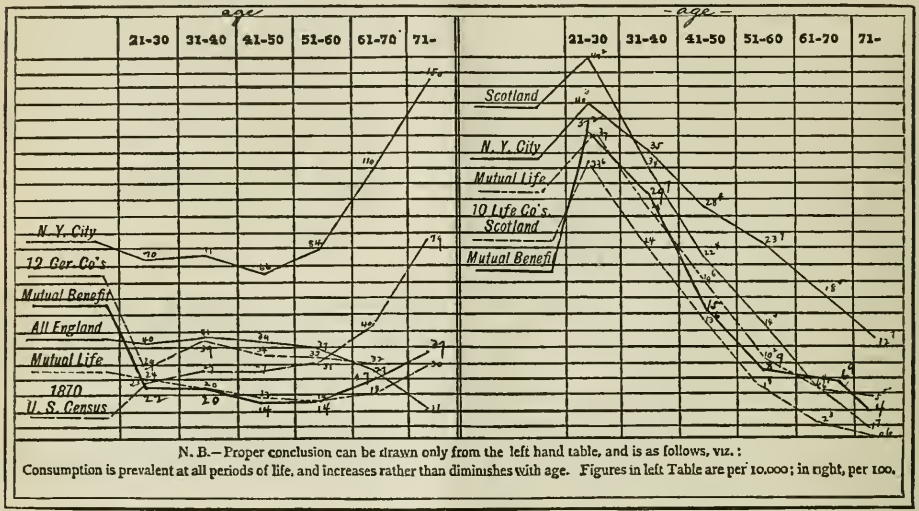
Rare facilities for prosecuting an investigation to obtain a correct result have led me with considerable labor to a conclusion as startling as I trust it will be found conclusive, viz., that death from consumption, instead of being, as is almost universally supposed, most prevalent in early adult life in this country is in reality not so, but grows relatively more frequent as life advances. This is true in the community at large, and among selected lives is actually less at the ages hitherto deemed most susceptible.

The figures dealt with have been so large as to make deductions from them secure, and the correspondence of result from the diverse sources enumerated in the table can leave no doubt of the correctness of the conclusion.

The experience of the population of New York City, of England, and of the United States in general, give the results for unselected lives and may be contrasted with the experience of life insurance companies which deal only with those carefully selected.

CONSUMPTION.

Showing the difference between actual and apparent mortality (adults only).



N. B.—Proper conclusion can be drawn only from the left hand table, and is as follows, viz.:
Consumption is prevalent at all periods of life, and increases rather than diminishes with age. Figures in left Table are per 10,000; in right, per 100.

The advantages derived by these companies from selection is manifest. The right hand table exhibits the results of the fallacious figures heretofore deemed trustworthy.

ON THE HEROIC USE OF CALOMEL IN DIPHTHERIA AND CROUP.

By I. P. KLINGENSMITH, M.D.,
BLAIRSVILLE, PA.

After having given the ordinary or expectant plan of treatment, including iron, quinine, chloride of potash, lactic acid, stimulants, etc., a faithful trial for eight years, and having had the usual high mortality rate, I began to look about for other remedies more definite and specific in their action.

About this time Dr. J. W. Anawalt, of Greensburg, Pa., called my attention to the success of the calomel treatment in his hands. Since then three cases have come under my personal observation, to which I will briefly call attention. In each of these cases the disease manifested as great a degree of malignancy as in many others treated in past years by the ordinary methods, which terminated fatally.

Case I.—On Sunday, April 10, 1883, I was called to see Amos McD——, aged twenty-eight months, of previous delicate health. Upon examination I found the pulse rapid and irritable, skin hot and dry, and the voice husky, with a croupy cough. The tonsils and a portion of the fauces were covered with a thick, tough, whitish-yellow exudation; while the glands at the angle of the jaws were somewhat enlarged and tender. I at once ordered twenty grains of calomel, which was followed by ten grains every hour, until the third day, when, the membrane beginning to separate at the edges, the mercurial was discontinued. During the first three days of the treatment, a total of seven hundred and twenty grains of

calomel were given, after which a solution of chlorate of potash was administered every two or three hours for a few days.

From the third day on there was a gradual improvement in the case, and by the sixth day the membrane had separated entirely. The recovery was rapid, and the exhaustion, so common in cases of such gravity, was entirely absent.

Case II.—On the afternoon of February 22, 1884, I was called to see Hulda H——, aged three and one-half years, of hitherto good health, who had then been suffering for forty-eight hours, during which time she had slept but little.

Upon examination I found a temperature of 102° F., rapid pulse, hurried respiration, croupy cough, extensive deposits, and congested face. I at once gave her twenty grains of calomel, which was followed by ten grains every hour for fifteen hours. A gradual improvement of the symptoms ensued after the administration of the first few doses, enabling the child to fall into a natural refreshing sleep. After discontinuing the calomel, the following mixture in drachm doses was given every two or three hours for a few days:

℞. Potass. chlor..... gr. xxx.
Ammon. mur..... gr. l.
Syr. prun. virg..... ʒ ij.
M.

By the fifth day convalescence was fully established, and the child made a rapid recovery.

Case III.—I was called to see Alice H——, aged four years on May 8, 1884. She had then been indisposed for upward of twenty-four hours. An examination revealed a high temperature, painful croupy cough, labored respiration, skin dry, face flushed with some diphtheritic deposits. I immediately administered twenty grains of calomel and followed with ten grain doses every hour until twelve doses were given, making a total of one hundred and thirty grains. In this case no other remedies were used, and in three or four days the child had fully recovered.

The mercurial used in these cases was the English calomel, and was given by filling a teaspoon half full of cold water, then dropping the medicine upon it, after which it was placed well back in the mouth of the patient. The calomel purges, but not to excess, causing simply free and copious evacuations of a greenish appearance. I have never known ptyalism to occur in a single case. My experience with this plan of treatment is based upon the three cases detailed above, besides a number occurring in the practice of other physicians. I am not one of those who claim to cure all my cases, but I do believe that with a faithful and proper administration of the remedy in question, disintegration and separation of the membranes will be facilitated, as well as relief afforded to allay the spasmodic character of the disease.

Differential Diagnosis of Simple and Tubercular Meningitis.—In an analysis of a number of cases of meningitis occurring in the Children's Hospital at Stockholm, Dr. O. Medin endeavors to formulate the points of difference in the tubercular and simple forms of the disease. Tubercular meningitis attacks only those children already suffering from tuberculosis of other parts, while simple acute meningitis occurs usually in previously healthy individuals. The former manifests its onset by convulsions, frequently strabismus, and dilatation or contraction of the pupils. Vomiting is frequent at the commencement, diarrhœa is the usual condition, and constipation is rare. The abdomen is never flat. The simple form begins with somnolence, twitchings, sudden changes of color in the face, and hyperæsthesia. More frequently than in the tubercular form we meet with the hydrocephalic cry and paralysis limited to the arms or to the face. The tubercular variety is always fatal in its termination—*Revue Médicale*, May 24, 1884.

Progress of Medical Science.

Splenectomy.—Dr. Koeberlé reported to the Société de Médecine de Strasbourg a case of extirpation of the spleen performed by him in April last. The operation was performed on account of hypertrophy consecutive to intermittent fever, the spleen measuring sixteen inches in length. The liver was also greatly enlarged, and there was an abundant serous exudation in the pleural, pericardial, and peritoneal cavities, together with œdema of the lower extremities. Despite difficulties occasioned by diaphragmatic adhesions, the operation, lasting over three hours, was successfully performed. The patient, having come from under the influence of the anæsthetic, was resting comfortably, when suddenly the eyes rolled convulsively, a few long inspirations were taken, and life became extinct. Death was supposed to have been caused by an intercranial hemorrhage.—*Journal d'Accouchements*, May 30, 1884.

Ergot in the Treatment of Constipation.—Dr. Granzio reports two cases of constipation, following the abuse of purgatives, relieved by ergot. Three doses of ten grains each were given at intervals of two hours, and were followed by a copious evacuation. A second stool occurred spontaneously the next day, and after the administration of ergot in smaller doses for a few days a definite cure was obtained. The constipation was due to atony of the muscular wall of the intestines.—*Allgemeine Medicinische Central-Zeitung*, May 24, 1884.

Chlorotic Fever.—About two years ago Dr. Humbert Mollière and F. Leclerc published the results of some thermometric observations made by them in cases of chlorosis, which seemed to indicate that this is a febrile condition. Since that time others also have observed the same thing. In the *Lyon Médical* of May 25, 1884, Dr. Mollière states that a further series of observations, in some cases extended through a period of eight months, has verified his previous conclusions, and established definitely the fact that chlorosis is a febrile disease and that the old name of febris alba virginum is strictly correct. The temperatures were taken with scrupulous regularity at the same times each day, and always by the rectum. In most cases there was a slight evening exacerbation, but in one instance the reverse obtained, the mercury being higher in the morning than in the evening. The average temperature was from 100° to 101.8°. Care was taken to exclude all cases in which there was even a suspicion of tubercular trouble. In some young girls, who were not chlorotic, but were simply anæmic from overwork or poor food, no elevation of temperature existed. In all the cases of true chlorosis there was a cephalic souffle, audible over the eyes on a level with the temples, and in some instances in the occipital region. This souffle was synchronous with a systolic murmur heard at the base of the heart and with bruits in the vessels of the neck. The febrile action was always in proportion to the intensity of the disease, subsiding gradually as the chlorotic condition disappeared. The urine in the cases examined was of normal amount, very light colored, sometimes containing a slight cloud of mucus, and never presenting any excess of urea above the normal quantity. Dr. Mollière leaves undecided the question as to the nature of this constant febrile reaction, whether it be a true pyrexia or of nervous origin, but inclines to the former opinion.

Antipyresis by Inunction.—Colbat favors a revival of the old method of Schneemann of inunctions with fat or vaseline in the febrile diseases of childhood. He uses cerate or vaseline in scarlatina, variola, broncho-pneumonia, and other pyretic conditions, and states that it reduces the temperature and induces a condition of restfulness. He denies that there is any danger of blood-poisoning in the employment of these inunctions.—*Medicinisch-Chirurgisches Correspondenz-Blatt*, May, 1884.

Borophenylic Acid.—A new series of experiments has recently been made to determine the antiseptic value of this substance. Borophenylic or phenylboric acid appears in the form of bushy needles, slightly soluble in cold water, but freely so in hot water, alcohol, and ether. It has a faintly aromatic odor, recalling that of marjoram. It has no caustic action upon the mucous membranes, even when applied in the form of powder, but excites merely a slight irritation. In fifteen-grain doses it causes ringing in the ears, vertigo, moderate headache and somnolence. Its antipyretic properties are said to be undoubted, and it would appear to be of greater efficacy than carbolic acid in arresting fermentation and putrefaction.—*Journal de Médecine de Bruxelles*, May, 1884.

Production of Paralysis without Anæsthesia by Peripheral Irritation.—Brown-Séquard, in experiments upon guinea-pigs, has found that when chloral is applied to the external auditory canal complete muscular paralysis without loss of consciousness is induced. When chloral is injected into the stomach the same effect is observed, though in a less marked degree. In every case the loss of the power of voluntary movements preceded anæsthesia and sleep. The experimenter supposed that a special influence was exercised upon the nervous centres, through irritation of the auditory, auricular, or other peripheral nerves, whereby muscular movement was abolished without loss of sensibility.—*Gaceta Médica Catalana*, May 31, 1884.

Repeated Attacks of Vomiting in Children.—This affection is one of early childhood. Vomiting occurs in attacks, coming on at varying intervals of time and lasting from a few hours to several days. The little patients are often greatly debilitated. There is frequently pain, sometimes intense, in the epigastric or umbilical region. The stools are irregular, sometimes abundant, sometimes scanty, and may be whitish or clay-colored. The causes are variable. The attacks may be due to exhaustion, to a nervous condition, to improper nourishment, or to the influence of cold. As regards treatment, a low diet, with or without chicken broth, is advised, and in addition calomel in small doses should be exhibited—*L' Union Médicale du Canada*, No. 3, 1884.

Prophylaxis of Puerperal Fever.—In his report of the Rotunda Hospital for 1883 (*Dublin Journal of Medical Science*, June, 1884), Dr. A. V. Macan recites in detail the method in vogue in that institution for the prevention of puerperal hetero-infection. Vessels containing a 1 to 40 solution of carbolic acid are placed over every wash-hand basin, and every one, before making a vaginal examination, is required to wash his hands in the solution, using a nail-brush carefully, and afterward dips them for half a minute in a 1 to 1,000 solution of corrosive sublimate. Every student or nurse who examines a woman *per vaginam* has to write his or her name down on a card, so that if the patient should afterward prove to be infected the origin of the infection may be traced. Only four students are allowed to examine any given case, and none who is dissecting is allowed to enter the hospital. There is an absolute rule against touching the woman's genitals with the fingers after delivery, except in cases of post-partum hemorrhage, ruptured perineum, or retained placenta, and then the assistant master only is allowed to make the examination. If any operation be necessary the vagina is irrigated and the external genitals are carefully washed in a 1 to 2,000 corrosive sublimate solution, and afterward the uterus is syringed out, and a suppository containing 3 jss. of iodoform is passed to the fundus and left there. Dr. Macan sees no necessity for prophylactic antiseptic injections if the fingers and instruments are perfectly free from septic poison, and consequently never uses them. Out of 1,090 women confined during the year but six died, and all these deaths followed more or less complicated labors. Not a single woman died who had a natural labor, nor was there a death among the 64 cases of forceps delivery, many of which were difficult extractions, and some undertaken before the full dilatation of the os. In the same report, Dr. Macan states that the temperature of every case was taken twice daily, and that he was unable to recognize any constant rise of temperature, even to the extent of one degree, accompanying the first secretion of the milk. Indeed, the temperature curve of the puerperal state, in a typical normal case, does not appear to differ in the slightest degree from that in the non-puerperal state. He is inclined to believe that any temperature above 100° F., except immediately after delivery, indicates that something abnormal is taking place, though it may not always be possible to say what the exact cause of the rise may be.

Hypodermic Injections of Calomel in Diseases of the Eye.—Dr. Rampoldi injects calomel subcutaneously over the temples in certain ocular troubles. He maintains that there is not only a specific action in the case of syphilitic affections, but that it also acts most efficaciously as a derivative in other cases. He has seen the pupil respond readily to atropine after these injections had been used, when before they were unchanged. The good effects of this procedure are often observed in those conditions in which leeches are indicated in which there is no suspicion of a specific taint.—*Recueil d'Ophtalmologie*, May, 1884.

A New Apparatus for the Relief of Deafness.—Professor Politzer describes in the *Wiener Medizinische Wochenschrift* of May 31, 1884, a little instrument invented by himself to aid those whose power of hearing is impaired. The principle is to transmit the vibrations from the pinna to the membrana tympani. Politzer opposes Voltolini's opinion that the cartilage of the ear is a poor conductor of sound, and on the contrary believes that the pinna, by means of its vibrations, is of great importance in the mechanism of hearing. His apparatus consists of a small elastic drainage-tube, one end of which is beveled off so as to rest evenly against the drum membrane, while the other end is curved slightly and by its elasticity presses gently against the anti-helix. Near its outer extremity the tube is attached to a small concavo-convex rubber plate. This plate is fitted so that its concave side lies in apposition with the concavity of the concha. The idea of this attachment is to increase the conducting power of the instrument and to transmit with greater facility the vibrations of the pinna. In a large number of experiments made to test the value of this instrument, the inventor found that in most cases the hearing distance for the voice was considerably increased, in some instances from two feet without to fifteen or twenty feet with the apparatus. In many cases the hearing distance for the watch was also increased, though in no such striking degree as that for the voice. In cases in which the drum membrane was partially or entirely destroyed, it was found necessary to attach an artificial drum to the inner extremity of the tube. In deafness due to anchylosis of the ossicles or to disease of the labyrinth, little or no improvement was obtained by the employment of the tube.

Action of the Intercostal Muscles.—M. Laborde has recently performed some experiments upon the cadaver of an executed criminal which would seem to have solved the problem concerning the action of the intercostal muscles. The body was obtained a very short time after death, while the electrical reaction of the muscles was still present. M. Laborde ascertained that contraction of the internal intercostal caused a narrowing of the thoracic cavity, while that of the external muscles caused an elevation of the ribs and an expansion of the chest. Hence the external intercostals are muscles of inspiration, and the internal of expiration.—*Revue Médicale*, May 24, 1884.

A New Edition of the Siamese Twins.—A case is reported in the *Hospitals-Tidende* of May 21, 1884, of twins born in a parish in Finland. Each child has its own head and the two upper extremities. From the united body two normally shaped legs are given off, and between them is the single genital organ (female). In addition there is a third leg, the foot of which is provided with eight toes. There are two anal openings. While one child sleeps the other may be awake and crying.

Paraldehyde in the Treatment of Delirium Tremens.—Dr. Gugl reports some additional cases of delirium tremens treated successfully with paraldehyde. The drug was given in the syrup and tincture of orange peel, and was taken readily by the patients, the taste and smell leading them to regard it as a particularly good quality of schnapps. The author asserts that paraldehyde is absolutely without danger in the dose of 1½ to 2 drachms per diem.—*Allgemeine Medicinische Central-Zeitung*, May 28, 1884.

Variations in the Size of the Pupils in Epileptics.—As a result of a number of observations, Dr. Giuseppe Musso concludes that: 1, The pupils of epileptics do not dilate to any greater extent than do those of healthy individuals; 2, in a large proportion of cases there is an habitual dilatation of the pupils of greater or less degree; 3, in a certain number of cases the epileptic attacks are preceded by an inequality in the size of the pupils, which inequality disappears when the fit is over; 4, although in certain cases of epilepsy inspection shows a greater sensitiveness of the pupils to the stimulus of light, yet this phenomenon is not of sufficient frequency to be of any special diagnostic value.—*Recueil d'Ophtalmologie*, May, 1884.

The Dosimetric Method of Administering Chloroform.—M. Peyraud takes a piece of fine cambric, and doubling it once, lays it on the face of the patient to be anæsthetized, covering only the mouth and nose. On the little bridge of cloth passing from the nose to the mouth he pours a single drop of chloroform, waits until an inspiration has been made and then pours another drop, and so he proceeds, putting on just one drop immediately after each expiration. At the end of some minutes, if anæsthesia is delayed, he increases the dose to two drops. Complete insensibility is obtained ordinarily in from seven to ten minutes. The writer claims that anæsthesia is produced by this method without any preliminary stages of agitation and hyperæsthesia, and without the occurrence of any irregularity in the pulse or respiration. When once anæsthesia has been obtained he withholds the chloroform for a minute or two, and then resumes its administration in the average dose of three drops per minute. The patients, it is said, find the chloroform given in this way not at all disagreeable to inhale, and so small is the proportion of chloroform in the inspired air (the vapor of one drop to 30.5 cubic inches), that there cannot possibly be anything to disturb the functions of hæmatosis or to irritate the respiratory mucous membranes. M. Peyraud cites several instances in which anæsthesia was produced and maintained during an operation with very small amounts of chloroform. In one case of an hysterical woman on whom an operation, lasting an hour and a half, was performed for cancer of the kidney, only 6¼ drachms of chloroform were used. It is assumed that the danger of arrest of the heart's action is, in this procedure, reduced to a minimum.—*Journal de Médecine de Bordeaux.*

In abstracting this article, a writer in the *Gazette Médicale de Strasbourg*, of June 1, 1884, states that the dosimetric method has been in vogue in that city for many years. Esmarch's apparatus, consisting of a wire mask covered with a piece of fine linen and fitting over the mouth and nose, is used. The air passes freely through the wire gauze on each side, while the linen serves to hold the chloroform. A contrivance is also employed by means of which the anæsthetic can be delivered drop by drop, with perfect accuracy, as required. The writer is in perfect accord with M. Peyraud as regards the great advantage possessed by this method of administering chloroform. He states that in a laparotomy recently performed, anæsthesia was maintained for three hours with the expenditure of one ounce of chloroform.

Tubercular Neuralgia.—In an article in *La France Médicale* of May 29 and 31, 1884. Dr. Ferdinand Dreyfous states that neuralgias are observed in tuberculous subjects in three different stages of the disease. 1. In the terminal stage they are, in the majority of cases, to be attributed to the cachexia which is a recognized cause of neuralgia in other conditions. 2. During the course of well-established phthisis we often observe intercostal neuralgia, or even tuberculosis of the phrenic or pneumogastric nerve. In these cases the painful nerves are in more or less intimate connection with the organ chiefly affected. 3. Finally, in the initial period we may meet with peripheral neuralgias in various parts of the body, but by far the most common is sciatica. It is not usually very troublesome and is frequently overlooked by reason of the attention being directed chiefly to the general condition. It is, however, not at all infrequent at this period of commencing tuberculosis, and has even been described as one of the early symptoms of the disease. Sciatica, when occurring at this stage, is usually unilateral, a point of some diagnostic value, since neuralgias of diathetic or toxic origin, as in diabetes and plumbism, are more commonly bilateral and symmetrical. The sciatic nerve is more frequently affected, it is supposed, partly because of its large size and partly by reason of its relatively abundant vascularity, which exposes it to greater danger of colonization by the micro-organisms.

Funnel-Shaped Thorax.—Dr. F. Percival relates an instance of this curious deformity in the *Rivista Clinica* for May, 1884. The subject was a man, forty years of age, whose family history showed a predisposition to phthisis, and one of whose sisters showed evidences of marked rachitis. He had himself always been healthy, and two children of whom he was the father were perfectly sound. The malformation of the chest had existed since birth, but had never caused any inconvenience on the part of either the heart or lungs. The excavation, shaped like a truncated cone, began at the junction of the manubrium with the sternum, and ended below at a distance of about five inches above the umbilicus. One could put his closed fist in the depression, and at first sight it seemed as though the sternum must touch the spinal column. The greatest depth was three inches, and the distance from this point to the spinal apophyses was scarcely four and a half inches. The aperture of the depression was of an oval shape, measuring six inches in length and four and a half in width. It was situated a little more to the right than to the left side of the thorax. Posteriorly there was a slight degree of kyphosis of the vertebral column, but no lateral deviation. Dr. Percival thought that the cause of the deformity was probably an arrest of development in the sternum, possibly due to a disease of the bones allied in its nature to the rachitis from which one of his sisters had been a sufferer.

Tubercles of the Breast.—The following are the conclusions formulated by Dr. Ghislani Durant in an article with the above title (*Gaillard's Medical Journal*, June, 1884): 1. The breasts may be the seat of tumors similar to the pathological products, found in many other organs, to which the name of tubercle is given. 2. Tubercle in the mammary gland is much more common than is generally supposed. 3. Mistakes as to the true nature of these growths have often been made, and ablation of the breast, from a belief in their cancerous nature, has often resulted. 4. During life we may by clinical observation distinguish these from other tumors. 5. As no absolute necessity for the ablation of these tumors exists, we should refrain from operating, unless unequivocal signs of malignancy develop.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 12, 1884.

CHOLERA AND ITS PREVENTION.

THE report that cholera has appeared in a seaport town of Europe sounds a note of warning which the health authorities of the United States would do well to heed. It is possible that the European States, with their experienced boards of health to guide them, and their well-equipped sanitary police to execute their orders, may prevent the spread of the pestilence on the continent. But whatever precautionary measures foreign governments may take to protect themselves, it will be the part of prudence to examine at once our own defences, and take such measures as will secure us against an invasion of the Oriental scourge. For we are, in truth, but little less exposed to an invasion of cholera than the cities contiguous to Toulon, owing to the constant emigration of the lower classes of that and other seaport cities of the Mediterranean to this country.

If we examine our methods of preventing the introduction and spread of contagious and infectious diseases of foreign origin in the light of modern science, knowledge, and experience, we can but conclude that they are cumbersome, expensive, and inefficient. Indeed, we do not hesitate to state that for the most part our machinery for protection against foreign epidemics was constructed, and is managed, in the spirit and enlightenment of the middle ages. Our quarantine system is still too much governed by the old idea, that time is the most important element in the destruction of the contagious or infectious germ, and that non-intercourse is the true method of preventing the propagation of the germs of epidemics.

Within the past two years the old *cordon sanitaire*, which is but another name for the shot-gun quarantine, has been the chief reliance of the highest functionary in this country to prevent the spread of yellow fever. Within the same period a vessel having on board hundreds of emigrants suffering from small-pox, has been detained in quarantine until the disease had completed its work, not a person being allowed to leave the ship in the meantime. This is only another method of enforcing the old dogma of non-intercourse, and is closely allied to the *cordon sanitaire* and the shot-gun quarantine.

The inadequacy of our present measures of prevention will become apparent if we reflect for a moment upon the present teachings of science as to our power to destroy in their incipiency the very germs of the diseases against which we create and maintain our costly and well-nigh useless quarantines. If cholera be taken as an example, we can readily determine how far in advance of our practice are the requirements of sanitary science. We now know that cholera can never invade this country, except the germs are, first, in the digestive organs of a human subject; or, second, are in his clothing, goods, or other effects where they have been lodged. With this knowledge as our guide, how simple and effective become all of our preventive measures! We aim to effect two objects, viz., first, to destroy the germ; and second, to prevent its introduction into the human stomach. The first is accomplished by the use of well-known germicides, and the second by care that neither by water, food, unclean hands, or other means, the germ enters the mouth. With a proper appreciation of these simple yet fundamental facts, we may apply preventive measures with precision. The cholera germ can be sought out and destroyed as absolutely as the spark of fire that would cause a conflagration. This was repeatedly proven during the outbreak of 1866 in this city, when scarcely two cases occurred in the same family, so promptly were remedies employed. An outbreak of cholera among the institutions on Blackwell's Island was in the same manner at once, and absolutely, suppressed by attacking the germs, and guarding the inmates against the ingestion of choleraic matters. It will be readily understood that preventive measures based on these principles wholly discard non-intercourse, whether enforced by *cordon sanitaire* or shot-gun quarantine. On the contrary, no other obstruction is offered to travel and traffic than what may be necessary to find and destroy the germs in transit.

Again we repeat that in the light of the above facts our quarantine system, and our quarantines at their best, will prove at present, as in the past, no effectual barrier against the introduction of cholera into this country. They are a delusion which serves a good purpose in quieting the apprehensions and fears of the public mind, but should no longer deceive the health authorities of this country, and especially of the great seaboard cities. Not a moment should be lost in the most thorough sanitation of these cities, and a vigilant supervision should be given to all forms of diarrhœal affections. We do not assume the rôle of alarmists, but would in all seriousness warn our health authorities that cholera in a seaport town of Europe always did, and now does, indicate that it is at our own doors.

The only system of preventive measures against epidemics of foreign origin which can ever adequately accomplish the purpose was partially organized by the National Board of Health. Had its powers been equal to the task we should now have a service which would be an impregnable defence against the invasion of cholera. That Board inaugurated the following scheme, viz.: 1. The co-operation of commercial nations in notification of the existence of pestilential diseases, in uniform and well-matured measures of defence and protection. 2. Sanitary inspection of every vessel at the port of departure, with power to detain and care for the sick, to secure absolute cleanliness of the ship, and to thoroughly supervise the cargo. 3. A sanitary service at sea which should isolate every form of contagious disease, destroy the first evidence of contagion, and pre-

serve the vessel, passengers, and cargo, in the best sanitary condition. 4. A series of insular refuge stations to which every infected vessel must resort before attempting to enter a port; this station was to be fully equipped with every appliance which science and experience could suggest for the cure of the sick, the cleansing of the ship, and purification of the cargo. 5. Local quarantines with every provision for the most exact expert examination of passengers, cargo, and vessel, as to the presence of the germs of disease. Such a service is practicable, and when fully perfected and put in operation will bring to a summary termination the roving pestilences which now infest the great lines of travel and commerce. But until this reform is accomplished local sanitary authorities must rely upon works of cleansing to remove every condition favorable for the reception and propagation of the epidemic, and by vigilant inquiry and inspection discover the first evidences of the presence of the disease, and destroy every vestige of contagion.

INFANTICIDE IN THIS CITY.

MURDER has always been looked on as the most heinous of crimes, and only to be expiated by the life of the murderer. This view, of course, is the one taken from the spirit and letter of the law. Although at times the object of the law is defeated through a variety of causes, the justice of capital punishment is seldom disputed. It happens at intervals that a very carnival of murder seems to pervade certain communities, and then the sense of outraged justice asserts itself, and the people demand the rigid enforcement of the provisions for its punishment. In New York City crimes have been committed, mysterious and horrible, like the Nathan murder, that have been for weeks and months the wonder of sensation lovers and the fear of the timid. The newspapers devote column after column depicting every minute detail of such tragedies as the one mentioned, and yet of another form of murder, more revolting if possible, there is seldom any mention made, or if there is it takes the shape of a three or four line item.

Suppose in the space of four months and a half the police had picked up, in various parts of Manhattan Island, the bodies of forty-five unknown men and women who had met death by violence, starvation, or exposure at the hands of parties unknown? Would not the public heart almost congeal with horror to think of the awful saturnalia of homicide being carried on in the city? Would not the citizens of New York demand, in tones not to be misunderstood, that every effort should be used to bring the murderers to justice? There has not been in the time mentioned that number of adult bodies found, but there has been of children ranging in age from a few hours up to two months. In February there were three found, in March seven—three on one day, the 28th; in April eight; in May *twenty-one*, and in June up to the 20th of the month, six. To give some idea of the extent of territory covered by these figures, it is enough to say that eighteen police precincts, Central and Riverside Parks, are represented. These statistics are from the Coroners' records and are presumed to be correct, and do not include any cases of fœticide; neither are any included of which there is the least knowledge in regard to either parent or of the child previous to the finding of the body. These forty-five are absolutely unknown, and almost certainly the victims of infanticide. The Coroners have held inquests in all the cases and found that death has resulted from many causes, but beyond drawing the fees accruing it cannot be said that they have done anything in the premises. Indeed, it is hard to believe that they do not consider the frequency of this fearful crime in the nature of a special dispensation rather than a sad commentary on the decaying morals of a civilized people.

The police, too, apparently regard infanticide as a necessary evil, and make no attempts to discover the perpetrators; or if they do make such efforts, they are only perfunctory and are given up almost as soon as started. They have a most peculiar method of reasoning in explaining their luke-warmness in ferreting out this species of murder. Their argument is, in effect, that the ones who commit the crime are so cautious and circumspect in disposing of the evidence in another part of the city from that in which the crime was committed, that it would be useless to attempt to discover the author. Strong logic, truly! The crime of murder can be engaged in with impunity if the murderer will only act with discretion! The reasoning is too diaphanous, however. There is in most of these cases a strong thread of evidence to begin with, which, in the hands of one who cared to use it, could be turned into a mighty cable, or at least into a hempen rope strong enough to sustain in mid-air the fiend or devil cruel enough to destroy a defenceless child. The claim that evidence is hard to obtain might be listened to, were the facts different and the finding of a child's body a rarity; but it seems supremely silly to set up such an excuse when the instances are so widely scattered throughout the city and of such alarming and amazing recurrence. Some parts of the city seem to be favorite and selected repositories for murdered children; one of these delightful spots is that part of the Eighteenth Precinct situate between Twenty-third and Twenty-fifth Streets and First and Second Avenues. This vicinity has been selected, no doubt, on account of its propinquity to the Morgue, and such little incidents serve to show the tender consideration of these pleasant people to whom abortion is a recreation and child-murder a pastime.

On the night of May 1st a party of boys found the body of a child in a marble-yard on Twenty-third Street, near First Avenue. An officer of the Eighteenth Precinct brought the body to the Morgue. It was about five weeks old, and about its neck and face showed signs of death from either suffocation or strangulation. It was well clothed and had been placed in a coarse bag with a paving-stone weighing ten or twelve pounds. Manifestly the intention of the party leaving the body in the marble-yard was to await an opportunity to drop it in the East River. In answer to an inquiry made by a reporter the sergeant at the desk in the police-station said that the case did not amount to anything, and even if it was infanticide, it would be impossible to obtain any clue. The following night another body was found a block distant from where the first was. Two nights after a third dead child turned up within a stone's throw of the police station. Three cases in four days! and yet there was

nothing to work on! It is safe to say that any reporter who had taken a case with as good points as these would never hold up his head again had he not worked them to a successful conclusion. Further than this, leaving out of the question the evidence furnished by the circumstances attending the finding of each body, there is the undeniable fact that no child is born without some one knowing of the birth beside the mother, and it is rank foolishness to assert that the child can disappear and only one person be acquainted with the circumstance.

But the police do injustice to their detective abilities. The real reason they make no effort to unearth the murderers of children is not the lack of evidence but the lack of inducement. These poor murdered children never had the right to exist, and if they are made away with no one grieves or pines. The unhappy mother is rid of a burden, the father of a stumbling-block, and the world of a bastard. The child itself is better off too, is the argument of the practical. All of which may be true—but shame on a social system which makes infanticide possible by teaching that it is a crime for a child to be born!

It is undoubtedly correct to say that nine-tenths of the people who ever give a thought to the subject feel a throb of pity for the so-called unfortunate mother who destroys her child. These mistaken soft-hearted persons seldom stop to consider that in many cases the mother does not do the job herself, but contracts for it through the agency of a baby-farm. Probably many of these dead children are the offspring of women living a disreputable life, who through negligence or ignorance have allowed themselves to become mothers. Pity is wasted here at least. Even if the mother is a young girl who has listened to the seducer, no excuse can be invented to cover up her fault when she becomes a murderess. Leaving speculations and arguments aside, one truth stands out in bold and horrid relief, and that is that fœticide and infanticide are looked upon to-day with a feeling nearly akin to indifference. When a Christian people have reached that point where they are not susceptible to such insidious attacks on the very basis of all morality, it is time to sound an alarm and insist on the enforcement of the statute law relating to murder, whether the victim be the offspring of a person of mark or only the unfortunate illegitimate child of a common woman.

TEMPERANCE PHYSIOLOGY IN THE PUBLIC SCHOOLS.

Publishers, in this and other cities, of text-books for schools are brought to face a curious result of the present energetic work of the temperance agitators. Writers or editors of school-books on anatomy, physiology, and hygiene are compelled to pay especial attention to the poisonous and demoralizing effects of alcohol and tobacco. In order to get a physiology accepted, the essential requisite is not that it be a good text-book, but that a disproportionate space be given to these subjects, and that statements be made which are hardly borne out by facts or in accordance with the conclusions of science.

It may be seriously questioned whether it is wise, after all, thus to inject temperance tracts into the body of a science text-book. In the long run it pays best to tell and teach the exact truth. And we are quite sure the exact truths regarding alcohol and tobacco are sufficiently terrible to impress duly the child. To say, as some text-books seem to do, that alcohol is a poison and a deadly poison, that it causes catarrhs, sclerosis, dropsy, crime, insanity, and shortened lives, and that moderate indulgence is an impossibility, is to present only one side of the picture. When the young student grows up and finds whole nations indulging in alcohol habitually, with no excess of drunkenness, and when he learns other features of the reverse of the picture, the results of his one-sided instruction may easily prove to be bad. Medical men are agreed that alcohol is a poison to youth and to those of hereditary taint, that it is dangerous in manhood, but is helpful in declining age. They also see that moderate drinking with the meals is a possible and often useful practice.

Is not this enough to teach, without making our school text-books the organs for an intemperate and dangerous fanaticism?

ANÆSTHETICS IN ST. PETERSBURG.

It is always interesting to learn of the practical methods employed by physicians and surgeons who live in distant countries and under different conditions from our own. At a meeting of the society of St. Petersburg physicians in January last, a large number of members contributed their experience in the use of anæsthetics, and we believe that an account of the opinions expressed will be instructive. It will be seen at once that the St. Petersburg profession is still in the chloroform era of anæsthesia. This is generally the case in those parts of Europe in which the life of the lower classes is esteemed of rather small moment.

Dr. Schmitz began the discussion by saying that in the Children's Hospital of the Princess Oldenburg a doubly rectified chloroform was used, and that even in operations lasting an hour and a half no bad effects had been observed.

Dr. Wulff said that at the Obuchow Hospital commercial chloroform was employed. In the case of alcoholic patients it was customary to give a preliminary hypodermic injection of morphine to facilitate the anæsthesia. Severe collapse in the use of chloroform was not often observed. A few cases of death had occurred, but it was doubtful if the chloroform was the cause.

Drs. Hirsch and Petersen related cases of obstinate resistance to anæsthesia. Dr. Hirsch's case, a very feeble man, failed to be affected by an ounce and a half of chloroform.

Drs. Moritz and Schmitz related histories of cases of pronounced heart disease in which chloroform was given without harm.

Dr. Hirsch thought that in cases of heart disease the chloroform might kill when given a second time if it did not the first, and instanced an illustrative case in his own practice.

Drs. Moritz, Petersen, and Hintze all thought that some of the cases of sudden death after administration of chloroform were the results of psychical influence. Several cases were referred to in which death suddenly occurred on the application of the knife, although no antiseptic had been given.

Dr. Holst thought that preliminary morphine injections did not act well. They caused an unquiet narcosis.

Dr. Monastyrski thought that these injections made the stage of excitement shorter, but that in the stage of narcosis there was more danger of asphyxia. He had had much better results with the doubly purified chloroform than with the commercial article. He had given chloroform to patients with heart disease several times with no bad results.

In reply to a question as to the age at which it is safe to give chloroform to a child, Dr. Wulff said that he had given it twelve times in one day to a child under two weeks of age. Dr. Schmitz had administered chloroform to a baby twelve days old, and performed an amputation under its influence.

Dr. Magawly had used chloroform in hospital and private practice for many years. He had only met with two deaths, both occurring in weak and emaciated patients. Autopsy in one case revealed a fatty heart.

NEW METHODS OF TREATING EPILEPSY.

A WRITER in the *Berliner Klinischer Wochenschrift* has used perosmic acid in the treatment of epilepsy, giving it in full form in doses of .002 milligr. He has had but little success, a few cases only having notably improved. He, however, thinks the remedy worthy of further trial. Bourneville and Bricon have recently reported the results of their experience in treating epilepsy with sclerotinic acid. They gave it in daily doses of 10 ctgr. gradually increased to 25. Among twelve patients thus treated, amelioration was obtained in only five. The drug is a failure as an anti-epileptic.

Professor William Pepper has delivered several clinical lectures upon the treatment of epilepsy in children. He calls special attention to the value of careful regulation of diet, of removing all sources of irritation, and of securing rest, including plenty of sleep.

In a series of experiments on chronic epileptics, Professor Henry C. Wood found that bromide of hydrogen (hydrobromic acid) decreased the number of fits more than the other bromides. He gave it in doses of ʒ j. to ʒ iij. daily.

Dr. S. Hughes Bennett, while offering no new remedy for epilepsy, has recently published statistics which show, as he thinks, that under bromides attacks are stopped in 12.1 per cent. of cases, are lessened in 83.3 per cent., and are increased in 2.3 per cent. He also believes his experience to show that the continued use of the bromides exercises no deleterious mental or physical effect except in a small proportion of cases. He thinks that epileptics can take bromides better than other persons, and that in course of time the eruptions and the depression disappear.

The experience of Kunze, who claims to have cured nine epileptics out of thirty-five with curare, has not been repeated by others. Curare has almost uniformly failed to effect any real benefit in epilepsy.

Ball, in addition to the use of bromides, belladonna, and zinc, advises the use of leeches to the mastoid process, and cathartics, in order to correct cerebral congestion.

Little has ever been done for epileptics by the use of electricity. The recent very favorable expression as to its value by Erb may, however, lead to further and more careful trials.

The experiments of Bourneville with the bromides of gold, camphor, arsenic, etc., show that not so good results can be obtained by these preparations as by the ordinary bromide compounds.

Continued contributions to the therapeutics of epilepsy only show that almost any new remedy can produce some temporary amelioration of the disease. But nothing at all approaching in value the bromide compounds as anti-epileptics has yet been discovered.

HIGH FEES IN DENTISTRY.

THE astonishing statement appeared a few days ago in the daily press that a dentist of this city had charged a fee of seven thousand dollars for four days' work in dentistry. It appears that the patients were three wealthy ladies of one family, and that the operators were father and three sons. Time consumed four days, with some extra work after hours. Value of time-work $50 per hour for each gentleman. So much can be learned from the reports referred to. The gentleman, a foreigner, to whom the bill has been sent, thinks there must be some mistake, and asks for explanations. Being assured to the contrary by the operators, he is more astonished than ever, and refuses to pay the amount.

On general principles skilled labor deserves to be well rewarded, but even that has a standard within easy range of ordinary imagination. When applied to dentistry it is hard to associate teeth-pulling, teeth-filling, and plate-making with such extraordinary or special skill as would place the value of services so disproportionately high as compared with similar work in any other mechanical grade. It is safe to say that no difficult capital operation in surgery, upon the skilful performance of which would depend the actual life of a patient, could command such a fee; nor, indeed, would any approach to such a sum be charged by any conscientious or reputable surgeon. And yet the dentist, whose responsibilities are nothing, and whose skill at best in his ordinary vocation of teeth-plugging is equal to that of a first-class mechanic, can charge a fee which would put to blush the most ambitious professional money-getter, and astonish the capabilities of a millionaire.

THE HURST PERFORMANCE.

THE Georgia Wonder, Miss Lulu Hurst, has been exhibiting her alleged wonderful powers in this city during the past week. We may say at once that she failed to satisfy the intelligent and critical among her audiences that she possessed any occult force whatever. The remarks which we made concerning her in a previous editorial were perfectly justified by a careful personal examination of her exhibitions. The "new force" acts only through the muscles of Miss Hurst and those experimented upon. It is, in fine, muscular force, and that is all. Miss Hurst is a strong, large-framed girl, and has the power of very rapidly contracting her muscles. A man takes hold of a cane with two hands and is told to hold it still if he can. He immediately throws his muscles into a state of extreme tension; Miss Hurst

then lays her big hands on the cane, with the thumbs underneath, we are told. By very slight but rapid muscular movements the cane is twitched around. The more the man resists, the more tense his muscles, and the more easily the cane is pushed about. Soon the man becomes excited; he thinks he is wrestling with a force, and performs various ludicrous gyrations. Miss Hurst ingeniously makes him labor and perspire over nothing. This is the sum and substance of all the experiments. No test upon an inanimate object shows anything at all. In keeping a chair from the floor, she holds it in a peculiar way, and apparently exerts her own not inconsiderable strength.

If Miss Hurst, as is possible, is not consciously deceiving, then it would seem as if the contact of her hands with umbrellas, chairs, and billiard cues produced a kind of artificial chorea. The phenomena she exhibits and calls out, are, at any rate, interesting perversions of the psycho-motor sphere.

They are still more interesting as illustrating the credulity and the utter incapacity for scientific examination of such performances which have existed among most of her audiences. We understand, however, that the true nature of her "force" has been exposed since her arrival in this city.

News of the Week.

Death of a Doctor from Chloroform.—Dr. MacRae, of Scotland, was suffering from a tumor at the nape of the neck, for the removal of which he went to Edinburgh, and placed himself under the care of Professor Annandale. While the chloroform was being administered prior to the necessary operation, Dr. MacRae, who was in the prime of life, suddenly died.

Memorandum for the Prevention of Cholera.—The State Board of Health has issued a memorandum regarding the measures to be taken to prevent the introduction and spread of cholera in this country. The Board consider it probable from past experience that cholera will reach this country, and they recommend the most careful disinfection and cleansing of our cities and towns.

Progress of the Cholera.—The deaths from cholera at Toulon and Marseilles have been slowly increasing in number daily from July 1st to 8th, as follows: July 1st, Toulon, 6; Marseilles, 3. July 2d, Toulon, 5; Marseilles, 4. July 3d, Toulon, 13; Marseilles, 5. July 4th, Toulon, 4. July 5th, Toulon, 7; Marseilles, 12. July 6th, Toulon, 4; Marseilles, 15. July 7th, Toulon, 9; Marseilles, 16. July 8th, Toulon, 10; Marseilles, 14; Nice. 1 (?). The total number of deaths from cholera at Toulon since the beginning of the epidemic is 154. The number of cases in the hospitals at Toulon has been between 115 and 150. Despite the number of cases at Marseilles the death-rate of the city is low, and it is believed that a great deal of needless alarm exists. Dr. Koch has arrived at Toulon, and has found the bacillus of cholera in the intestines of those who have died from the disease. He pronounces it Asiatic cholera, therefore. He is reported to have stated that it would spread to Germany; also that the germs of the disease were taken into the system in food and drink, not by inhalation. While the Spanish, Italian, and Austrian Governments have instituted quarantine against vessels from French ports, England refuses to adopt anything but her inspection system. A vessel from Marseilles with two cases of cholera on board is said to have been intercepted in the Channel. All passengers and baggage arriving at Paris from infected districts have now to be disinfected.

The Colorado State Medical Society met at Denver on June 19th, 20th and 21st. Dr. Whitehead, President, in the Chair. The following officers were elected for the ensuing year: *President*—Dr. Hawse, of Greeley; *Vice-Presidents*—Drs. Soly, Rogers, and Earhart; *Recording Secretary*—Dr. S. A. Fisk.

The Investigation of Lulu Hurst.—We have received a number of letters from Southern medical men protesting against our judgment of Miss Hurst's performances. We venture to answer them all here by publishing a letter written in answer to one of them by a gentleman who investigated the matter at our request: "Dear Doctor: Having been asked to investigate the Hurst phenomenon, I went and saw her last night. In common with the medical gentlemen with me, I thought she utterly failed to demonstrate the possession of any peculiar powers; the phenomena could all be explained, and easily, by assuming the existence of unconscious convulsive movements and by the peculiar muscular rigidity and expectant state into which those experimented upon got themselves. While perfectly willing to be convinced, we saw nothing to justify us in assuming a new force, but only a curious disturbance of the voluntary motor system, and an interesting illustration of what may be done with persons in a state of expectancy and great muscular tension. Some of her experiments were subsequently repeated among ourselves. Miss Hurst does indeed cause dead matter to move, but no more than any large and muscular girl could make it."

Disinfection of Rags from Egypt.—The following are methods of disinfecting rags which are considered satisfactory by the Treasury Department: 1. Boiling in water for two hours under a pressure of fifty pounds per square inch. 2. Boiling in water for four hours without pressure. 3. Subjection to the action of confined sulphurous-acid gas for six hours, burning one and a half to two pounds of roll brimstone in each 1,000 cubic feet of space, with the rags well scattered upon racks.

Local Health Officers and Inspectors of Customs.—The Treasury Department has decided that State Health authorities cannot prevent United States Inspectors of Customs from landing at quarantine stations and pursuing their duties there, if necessary. The question came up at Charleston, S. C.

Experiments with a Decapitated Human Head.—M. Labarde has been making some truly ghastly experiments with the head of Campi, the murderer, who was recently executed in Paris, and in the *Revue Scientifique* he publishes an account of them. By means of a tube he connected the carotid artery of the head with the corresponding artery of a living dog, and the head being placed upright on a table, the stop placed on the dog

was removed. As the blood was carried into the head the livid hue of the face disappeared and color returned, the forehead and cheeks being suffused and the eyelids moving. Some time had elapsed since Campi's death, and M. Labarde regrets that such experiments cannot take place immediately after execution, as the physiologist might thus be able to witness a "grand and terrible spectacle."

Dr. Martin McGovern has been appointed Police Surgeon, *vice* Dr. M. H. Henry, resigned.

New Method of Supporting the U. S. Marine Hospital Service.—The last Congress passed the following law: "That sections forty-five hundred and eighty-five, forty-five hundred and eighty-six, and forty-five hundred and eighty-seven of the Revised Statutes, and all other acts and parts of acts providing for the assessment and collection of a hospital tax for seamen, are hereby repealed, and the expense of maintaining the Marine Hospital Service shall hereafter be borne by the United States out of the receipts for duties on tonnage provided for by this act; and so much thereof as may be necessary is hereby appropriated for that purpose." The sailor is, therefore, no longer taxed forty cents a month, and the marine hospital service is supported by the owners of vessels, instead of by their employees. The question may now be raised, whether employers can constitutionally be taxed for the support of their employees when sick.

Gifts to Hospitals.—The sum of two million francs was bequeathed by the late Baroness Alquier for the erection of a new hospital in Paris. The London Hospital has just received $50,000 from Baroness Rothschild.

Membership in the American Medical Association.—At the meeting of the American Medical Association, held at Washington in May last, an amendment to Regulation II. was adopted, which provides that "Membership in the Association shall be obtainable by any member of a State or County Medical Society recognized by the Association, upon application, endorsed by the President and Secretary of said Society; and shall be retained so long as he shall remain in good standing in his local Society, and shall pay his annual dues to the Association."

A Religious Quack Advertisement.—As a specimen of the means by which the simple are induced to part with their money, the following, says the *Student's Journal*, cut from the advertisement columns of *The Christian Million*, is worthy of perusal: "The Bitter Cry for Help.—Thousands of God's creatures are lifting up their plaintive voices for help. Poverty presses hard upon them, and renders their lives a sad monotony. Living in narrow dwellings, and constantly breathing impure air, they are physically weak and altogether unfit for the duties of life. Sickness and suffering, hunger and ignorance, are, as it were, written on the very doorposts of their dwellings. In higher circles we find a different state of things—no poverty, no badly-ventilated homes; but many afflictions, nevertheless, weigh upon them, symptoms of ill-health which their physicians appear to be unable to remove—failing sight, deafness, noises in the ears, indigestion, coughs, and a variety of other complaints, make these well-to-do people very, very sad. From all classes comes up the cry for help. The man who has the power to help his brother and is unmindful of his trust is surely unfaithful to the better promptings of his nature. The noble army of faithful workers, ministers, doctors, and sick visitors, deserve our prayers and sympathy. The Rev. E. J. Silverton, has for many years been engaged in alleviating the sufferings of mankind, curing deafness and removing noises from the ears by means of his 'Aural Remedy,' curing indigestion and all its tortures by his 'Patent Pills,' and building up broken-down constitutions by his 'Medical Energiser and Magic Cough Mixture,' and his 'Nutrient Food of Food.' All these wonderful medicines may be ordered of any Chemists, who will procure them for any sufferer. The prices are arranged to meet all classes, viz., 'Patent Pills,' 1s. 1½d., and 2s. 9d. per box," etc. Were any ordinary quack to use the name of the Supreme Being for trade purposes it would be considered rank blasphemy, but, in the case of a "Reverend" it is doubtless accepted by *Christian Million* readers as a guarantee of good faith.

An Epidemic of Typhoid Fever in Switzerland.—Typhoid fever has been very prevalent in Zurich, a city of 83,000 inhabitants. The disease has been characterized by severe complications. One of the causes is thought to have been the low water in the lake.

Journalistic Changes and Evolution.—The progress of evolution is said to proceed from the homogeneous, the simple, and the undifferentiated, to the heterogeneous and complex. Exactly the reverse occurred, nosologically speaking, when the *Kansas and Missouri Valley Medical Index* and the *New Medical Era and Sanitarian* consolidated under the plain and undifferentiated title of the *Medical Index*.

Religion and the American Doctor.—Nothing for a long time has so stirred up the religious sentiments of the American physician as a resolution introduced into the American Medical Association last May, proposing to dispense with the opening prayer. Most of our contemporaries have made vigorous comments expressing approval of the action of the Association in promptly tabling the matter. No one has put it quite so vigorously, however, as the energetic editor of the *Texas Courier-Record*, who concludes his criticisms of the injudicious introducer as follows:

"Oh, shame, where is thy blush? Oh, cheek, where is the limit to thy flintiness? Oh, immaculate gall, assurance, impudence, thy name is ——— him who insulted that grand body of grave, thoughtful, earnest workers, whose very lives and presence testify the existence and providence of the living God, and belie and belittle your puny doctrine."

It is no discredit to the heart of our esteemed contemporary that he subsequently confesses to having received the consolations of refreshment.

Third Congress of the Italian Surgical Society.—The third Congress of the Italian Surgical Society will be held in Turin on the 15th to the 20th of September, 1884. The secretaries are Drs. G. Novaro and G. Berruti, of Turin.

The French Association for the Advancement of Science meets at Blois on September 4 to 11, 1884.

Vivisection Work in England.—A return which has just been published showing the number of experiments performed upon living animals during the year 1883 under the Vivisection act, is a somewhat remarkable document. It appears that in England and Scotland 44 persons have held licenses under the act during some part of that year, of whom 32 performed experiments and 12 performed none. In Ireland 8 persons held licenses, of whom only 4 performed experiments. The total number of experiments of all kinds was 535 in England and Scotland, and 34 in Ireland. Of these 290 were carried out under the restrictions of the license alone, 55 under special certificates dispensing with the use of anæsthetics, and 122 under certificates dispensing with the obligation to kill the animal before recovering from anæsthesia. Under certificates permitting experiments on cats, dogs, horses, mules, and asses there were 102 operations, but it appears that only four or five were upon cats or dogs, and none at all upon the other animals named. As regards the 290 cases first mentioned, together with a number carried out under certificates prescribing anæsthetics, the animals were rendered insensible during the whole of the operations, and were not allowed to regain sensibility. Their sufferings were accordingly quite inappreciable by the most acute sympathizer. The 55 experiments without anæsthetics consisted in simple inoculation or hypodermic injection with morbid matter whose operation it was desired to discover, and the pain inflicted was at the most that of ordinary vaccination and its results. Of the 122 experiments in which the animals were allowed to regain sensibility, 114 also consisted principally in inoculation, and were for the most part connected with an important inquiry into the nature of tubercular affections. No pain was inflicted save in some 14 or 15 instances, and even in these it was trifling. In the remaining eight cases anæsthetics were used, and though the surgical operations amounted to more than a mere puncture, the pain would be only that usually attending the healing of a surgical wound. The experiments upon cats and dogs are classified under the heads already mentioned. The conclusion of the Inspector's report is that "the amount of direct or indirect suffering from the performance of physiological experiments during the past year was wholly insignificant, and limited to about 14 or 15 animals."

Water and Constipation.—Dr. Squibb, in his last *Ephemeris*, has a suggestive article upon constipation. He thinks that most constipations are due to insufficient water in the fecal mass. The individual does not ingest enough water to supply the blood with its seventy-nine per cent., therefore the blood absorbs it from the intestinal contents. "Drink water," is Dr. Squibb's motto. It is a good one; but water, as every one knows, will not cure habitual constipation in a very large percentage of cases.

Dr. Axel Iversen.—The name of the surgeon associated with rectal etherization should be written Iversen, not Yversen. It was incorrectly spelled in the *Lyon Médical*, in which Dr. Mollière's notice appeared, probably through the writer's attempt to represent the Danish pronunciation by the French spelling.

Reviews and Notices.

The Physician's Combined Day-Book and Ledger. By H. T. Hanks, M.D. New York: J. H. Vail & Co. 1883.

To the average physician, who knows as little of bookkeeping as he does of navigation, one of the greatest trials of his life is the keeping his accounts straight, and anyone who helps to simplify and lighten his labors in this direction may justly be regarded as a benefactor to the profession. And after a practical trial of the system here presented we are disposed to grant this title to the author. In this book provision is made for the date and character of the visit, the member of the family attended, special charges, etc., all within the smallest possible space. The charges can be continued from month to month or year to year without re-entering, and the entire account of each patient may be comprehended at a glance. The necessity of a ledger is done away with, thus saving the physician much time and avoiding all possibility of error in making the transfer. The author "claims to have arranged in this book the most exact and labor-saving system of book-keeping ever devised for the use of a physician," and as far as our experience will permit us to judge we think his claim is well founded.

Elements of Pharmacy, Materia Medica, and Therapeutics. By William Whitla, M.D. (Q. V. I.), Physician to the Belfast Royal Hospital; Consulting Physician to the Ulster Hospital for Diseases of Women and Children; Vice-President of the Ulster Medical Society, etc. With Lithographs and Woodcuts. Second Edition. London: Henry Renshaw. 1884.

This manual, intended primarily for students, contains a vast amount of practical information arranged in very convenient form for ready reference. It is divided into six parts, treating of pharmacy, materia medica, therapeutics, non-official remedies, prescription writing, and chemical reaction, with some of the more important tests. The arrangement of the drugs is in alphabetical order. There is an index of poisons and their antidotes, and a very copious general index adds to the value of the work as a ready-reference manual. The fact that a large edition was exhausted within two years is a sufficient evidence that the book has supplied a want.

Hand-Book of Eclampsia, or Notes and Cases of Puerperal Convulsions. Comprising all the Cases which have occurred during the Present Century within a Radius of Several Miles around Avondale, Chester Co., Pa., so far as can be ascertained. By E. Michener, M.D., J. H. Stubbs, M.D., B. Thompson, M.D., R. B. Ewing, M.D., and S. Stebbins, M.D. Philadelphia: F. A. Davis. 1883.

The authors of this little *brochure* have collected and studied forty-four cases of puerperal convulsions occurring during the present century in the vicinity of Avondale, and have here presented their conclusions derived from this study. Briefly stated, their belief is that the proximate cause of puerperal eclampsia is hyperæmia of the brain, and the treatment based upon this belief consists in prompt and plentiful bleeding. The essay will repay a careful perusal, even though the conclusions of its authors may not be accepted in their entirety.

Female Hygiene and Female Diseases. By J. K. Shirk, M.D., Member of the Lancaster City and County Medical Society. Lancaster, Pa.: The Lancaster Publishing Co. 1884.

This is a book intended for the laity, and treats in intelligible language of the hygiene and diseases of the female reproductive organs. It contains much useful information on a subject of which women are often too ignorant, but we think it would have been productive of more unmixed good and would have served an equally useful purpose had the directions concerning the medicinal treatment of disease been omitted.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 11, 1884.

R. E. Van Gieson, M.D., Vice-President, in the Chair.

Dr. Wackerhagen presented specimens as follows: The first was one of

CARCINOMA OF THE BREAST

removed from a German woman seventy-two years of age. Twenty-five years ago she noticed a small lump in the breast, which gradually enlarged but caused no inconvenience until two years ago, when it became painful. In December last a small abscess formed below the nipple, which continued discharging until the operation on May 18th. During a few weeks before the operation the pain was at times very severe, and she was anxious to have the tumor removed. It weighed nine ounces, and consisted of normal gland structure and adipose tissue, in the midst of which was a mass of fibrous tissue arranged in trabeculæ, which radiated in all directions, and in the meshes of which were free fat and probably some cell elements. To one side of the centre of this mass was a cavity whose walls were composed of the same fibrous material of a darker color, and from which could be expressed a thick greenish juice. This is probably a post-mortem change. To the touch the specimen was fairly firm, and presented nodular areas of small size throughout the mass. The smaller mass came from the axilla. It weighed about two ounces, and was composed of adipose tissue, lymphatic glands, and nodules the size of large chestnuts and composed of fibrous tissue arranged in trabeculæ which radiated in all directions, and in the meshes of which were cellular elements and some fat. To the touch the nodules were firm and fairly well defined. There were also blood-vessels disseminated throughout the mass, but apparently not in the nodules, at least of appreciable size. The dressings were bichloride and iodoform, and were not removed until the eleventh day, when complete union had taken place throughout.

EPITHELIOMA OF THE PENIS.

The second specimen was a portion of a penis removed from a gentleman aged sixty-four. He had suffered from irritation of the glans for several years, the result of phimosis. During the past year pain and itching had been very severe, and at times there had been considerable hemorrhage. The glands in both groins were enlarged, but had decreased greatly in size since the operation. The tendency of the growth seemed to be outward, rather than down into the deeper portions of the tissue. The urethra was apparently intact, excepting at the meatus. Upon the glans was seen a growth which extended from the meatus nearly to the corona glandis, or the point of junction of the glans with the cervix of the penis. This growth was soft, of a papillary or fungiform appearance, and seemed to involve, to a moderate extent, the normal tissue of the glans. A portion of the glans had been removed for microscopic examination. A similar growth was seen upon the prepuce, extending from the line of junction of the outer and inner surfaces downward on the inner surface for a distance vary ing from a scant half inch to an inch in length. It was nearly annular, forming almost a complete circle upon the inner surface of the prepuce. Upon the right side the neoplasm was gradually gaining the outer surface of the prepuce, over which it extended for a short distance.

The specimen was referred to the Committee on Microscopy.

LIPOMA OF THE NECK.

The third specimen was a lipomatous tumor removed from the neck of a young married woman, aged twenty-three. It was located posteriorly and to the right of the median line, and at a point nearly midway between the occipital protuberance and the vertebra prominens. It weighed sixteen drachms. The mass consisted of a fibrous capsule which gave off branches of fibrous tissue that filled the capsule in such a manner as to make it somewhat cavernous. Within the meshes of fibrous tissue was collected a large amount of fat, which gave to the mass a degree of compressibility. The capsule was quite thick, very tough, and vascular, as could be readily seen by the numerous ligatures on different portions of the surface. Sections of the mass float in water, giving evidence of its lipomatous nature. One or two small secondary nodules were observed around the periphery of the mass. These were similar in structure to the large growth.

The fourth specimen was an

ENCYSTED TUMOR OF THE THIGH

situated just below the greater trochanter, removed from a gentleman, aged twenty-six. The tumor was enclosed in a firm fibrous capsule which was partially covered with adipose tissue. On section a white caseous mass was seen, which was readily expressed with slight pressure. The cheesy mass was soft and mushy, disintegrating readily on pressure.

TUBERCULAR PERITONITIS—GENERAL TUBERCULOSIS.

Dr. W. P. Northrup presented a specimen with the following history: The patient was a female, inmate of the New York Founding Asylum, aged three years and ten months. She was brought in from the out-nurse in February, 1884. She was somewhat emaciated; had well-marked ascites; bowels inclined to be constipated; moderate bronchitis. Beyond these there were no noted symptoms. The ascites gave ready fluctuation, but on changing the position of the child the fluid did not move about readily—seemed to be encysted. Later, though the fluctuation continued it was less prompt and somewhat different in character.

Autopsy, June 10, 1884.—Body: Extremely emaciated, abdomen distended. Brain: Examination not allowed. Lungs: Bronchial and tracheal glands enlarged throughout, though none to a large size. Left lung is adherent over nearly its whole surface. In middle third posteriorly are two cheesy masses about the size of an ordinary hickory-nut. Aside from this the same description will serve for both lungs. Large, opaque, and glassy miliary tubercles are uniformly distributed throughout both. Between the tubercles is a moderate amount of diffuse pneumonia and well-marked œdema. Heart: Normal. Peritoneum: On opening the abdomen the muscular wall and the contents of the serous membrane are found glued together. The peritoneum is thickened and thickly sprinkled with cream-colored, rounded tubercles about half as large as a pea. The coils of intestine, large and small, liver and spleen and stomach, are tightly glued together into a fluctuating mass. Fluid, gruelly fæces escape before any artificial opening can be found. In dissecting open the intestines a coil can be followed for a few inches and then it dips down into the mass and is lost. The whole mass is then cut across and the half coils are found held in place by the gelatinous mass of tubercle and thickened peritoneum, so that the cut ends remain half patulous. Mesenteric glands have broken down into large cheesy masses. Numerous ulcers, large and small, are found. Many have perforated the wall of the intestine. Others are deeply sunk with overhanging edges. Liver: Peritoneal covering much thickened, and contains large tubercles. On section, a few ordinary miliary tubercles are found. Spleen: Same description applies to its covering, and the tubercles seen on section. Kidneys: One ureter dilated to nearly one-half more than normal size; three to five opaque white miliary tubercles found on cut surfaces.

Dr. Northrup said he had seen this condition of peritoneum in young adults, but never before in a child under four years.

Dr. Peabody thought the condition was not common in children, although sufficiently frequent in adults. Although large tubercles of the peritoneum were not common, large masses of tubercular tissue were likely to be found wherever tubercles had existed for a considerable length of time.

Dr. J. C. Peters said that some time ago he saw two cases, one in a child two or three years old, and the other in a child four or five years of age. The clinical history was peculiar in the fact that the only symptom present for some time was extreme irritability of the bladder. Afterward cerebral symptoms developed, and the existence of tubercular meningitis was evident and was supposed to be the principal disease. Both children died, after a sickness lasting about three weeks, and in each there were tubercles as large as those in Dr. Northrup's specimen, on the peritoneum, and tubercles in every organ seen; the brain was not examined.

Dr. Ferguson referred to a case of perforation of the intestine without definite symptoms, which he encountered at an autopsy not long ago, and in which the diagnosis of ovarian tumor had been made by several gynecologists. There was no ovarian tumor at all, but simply a dilated portion of intestine, which had ruptured and emptied the contents of a large sac into the peritoneal cavity without giving rise to any marked symptoms.

Dr. C. H. Knight presented a specimen with the following history:

TUBERCULAR MENINGITIS—HEREDITARY SYPHILIS?—BASILAR GUMMOUS MENINGITIS?

Jenny M——, aged one year, was first seen on March 24, 1884. Had been fretful and restless for a day or two, and had vomited once; slight febrile reaction; symptoms were thought to be due to irritation from an upper lateral incisor tooth which was beginning to come through.

Five days later I was called to see the child, whom I found lying with wide-open staring eyes, and apparently unconscious; head constantly rolling from side to side; gives a feeble cry or whine from time to time; takes no nourishment without rejecting most of it in a few moments; occasional twitchings of extremities; temperature normal, pulse slow and regular. Merc. inunc. and K. I., gr. j., every hour.

March 30th.—Pulse, 68, regular; temperature, 99½° F. in axilla; refuses to nurse; has taken little beef-tea and milk from spoon; lies most of the time apparently asleep, but the left arm is in constant motion between the side and the nose, as though trying to brush something from the face; left leg is occasionally drawn up; right side motionless and flaccid; rolling of head ceased; face pale; pupils contracted, left more than right—respond slowly to light; typical Cheyne-Stokes respiration; no vomiting; bowels moved naturally yesterday P.M.

March 31st.—Pulse irregular, 95; temperature, 100½° F.; respiration same as yesterday; pulse slows during intervals of non-respiration and accelerates with return of breathing; sleeps most of the time without moving; when roused moves only the left arm and leg; left cheek flushed, right pale; signs of iodism, hypersecretion nasal mucous membrane; occasional sneezing; congestion of conjunctivæ, especially right; no eruption.

April 1st.—Pulse, 130; respiration, 20; temperature, 101° F. Breathing is quieter and has lost the Cheyne-Stokes character; no movement of bowels for three days; urine passed naturally; pupils normal; no strabismus.

April 2d.—Pulse, 120; temperature, 99½° F.; respiration, 22 and more regular; intervals of rest occur only once in a minute or so; child seems brighter and is more easily roused; takes very little nourishment, but retains what is swallowed; when roused is fretful and makes a peculiar chewing movement of the jaw; movements of left arm and leg continued; has a vacant, staring expression, but the lids are closed when the eyes are approached by the finger.

April 3d.—Ophthalmoscopic examination attempted by Dr. Amidon; unsatisfactory view of fundus on account of incessant motion of eyeballs; apparent hyperæmia on left side; right eye wider open than left; occasional twitching of eyelids; eyeballs constantly moving up and down rather than from side to side; every few seconds left eye is drawn violently toward the nose by clonic spasm of the internal rectus; left pupil contracted, right normal or dilated and feebly responsive; child is entirely unconscious, but there is evident attempt to protect the eyes by closure of the lids when the finger or a bright light is brought near; right arm and leg motionless and flaccid, left arm inclined to be rigid; left thigh incessantly flexed and extended; extremities cold; head bathed in perspiration. Temperature, 99° F.; respiration shallow and irregular; period of rest for twenty to thirty seconds followed by a deep inspiration and an equal period of rapid breathing, at the rate of sixty or seventy to the minute; pulse, 140, irregular and compressible; bowels moved this morning after two grains of calomel; no nourishment nor medicine has been retained to-day; remained in above condition from 8 P.M. until 5 A.M. April 4th, when the patient gave a feeble cry and had clonic spasms on the *right* side lasting several minutes; then relapsed into previous condition and died quietly at 8 A.M.

For the report of post-mortem and for microscopic sections, I am indebted to Dr. Amidon.

Autopsy, nine hours after death.—Head of average size and good shape; calvarium very thin; anterior fontanelle open and depressed, about three centimetres square; scalp and dura fused at fontanelle. On cutting the optic nerves at the base, a quantity of fluid (120 (?) c.c.) escaped from the arachnoid behind the optic commissure, between the optic tracts and the crura and the under surface of pons and medulla. On removing the brain by section, just above the pons more fluid came from the iter and third ventricle. A diffuse gelatinous deposit covered the base about the optic commissure and tracts and about the points of emergence of the crura, also the under surface of the pons, and to a slight extent the medulla, also the peduncles of the cerebellum and the region of the cerebellum contiguous to the pons. This deposit was in places three millimetres thick, translucent, non-vascular, tenacious within the meshes of the pia mater, and with that membrane readily stripped from subjacent tissues—in many places its surface imparted to the finger a sensation of "smooth sand." The pons was compressed into a polygonal shape by the serous exudation, and its tissue was very hard; on section the pons and medulla appeared to be normal, with the exception of a dilated iter. The pia mater, on the convolutions at the base of the frontal, temporal, and occipital lobes, in the neighborhood of the gummy deposit, and especially about the optic commissure and between the olfactory tracts, was studded with miliary deposits of grayish-white color, not connected with the vessels, apparently beneath the pia yet stripping off with it. Convexity and substance of cerebrum normal. Lateral ventricles dilated. Ependyma of all the ventricles normal. No other viscera were examined.

Remarks.—It appears that the father contracted syphilis in 1877 (six and a half years ago, five and a half years before birth of this child). He was treated early and continuously for several years, and his symptoms have been mild, comprising induration of inguinal glands, erythematous and later small papular syphiloderm, and sore throat, all slight and transient and within the first eighteen months. About one year later infection of the mother occurred, and she was admitted to Roosevelt Hospital in July, 1878 (four and a half years before the birth of this child). She was treated for chancroidal (?) ulceration of the genitals and a syphilitic ulcer of the right forearm near the elbow, nine weeks in duration; about six weeks later she had an eruption and lost most of the soft palate by ulceration. Two and a half years ago she again had sore throat, ulcers on her legs, and at the same

time she lost the nasal septum and cartilage by ulceration. Since then she has had no symptoms and she now seems entirely well. Her treatment has been very imperfect and irregular. She has never had a miscarriage. During the first year of the mother's infection a child was born who is now living. He was quite healthy at birth, but nine or ten months later he had ulcers on his body and onychia. He is now strong and well-nourished but perhaps a little under size. The child from whom these specimens were taken was born during the fifth year of the mother's infection, more than a year subsequent to her final syphilitic manifestations. There were no lesions at birth, and when first seen by me the child appeared thoroughly well nourished. The teeth were normal in evolution, shape, and size, and the mother insisted that the child had never had any skin eruption or other sickness.

Microscopical examination made by Dr. Amidon. The tubercles consisted of collections of lymphoid cells, the central portion of the collections being dense and opaque. There is a general infiltration of the pia mater (at the base) with large polyhedral cells, larger than white blood-corpuscles. The translucent material at the base of the brain consisted of loose connective tissue holding the same cells in its meshes.

Dr. Amidon said that the case was interesting to him especially on account of the family history. It was supposed that the cerebral trouble was undoubtedly syphilitic in character, and, at the autopsy, the gross appearances resembled those given by syphilitic rather than tubercular lesions; but the microscope revealed that the lesions were tubercular. The existence of miliary collections of small cells over the base of the brain should have convinced them that the case was one of tubercular meningitis, but the clinical history differed so much from that ordinarily met with in tubercular meningitis, that it, together with the peculiar gross appearances, misled him.

Dr. Northrup remarked that nystagmus and the peculiar motion of the limbs noted were not uncommon in general tuberculosis; so also the gelatinous exudation at the base of the brain. He regarded the case as unusually interesting in connection with the syphilitic history.

Dr. Peabody said that the case was interesting to him because he saw a similar one last winter, occurring in an adult, in whom there was a distinct syphilitic history. As he recalled it there was no peculiarity in the symptoms.

At the autopsy he found a gelatinous exudation covering the base of the brain, and extending down upon the anterior portion of the cord, from an eighth to a sixteenth of an inch thick, but with it no pus whatever. Microscopical examination failed to reveal any tubercles, but in the neighborhood of the thick exudation he found considerable perivasculitis and evidence of arteritis obliterans, and the combination led him to believe it to be syphilitic in character. He thought it perfectly possible that in Dr. Knight's case syphilis and tubercular meningitis co-existed.

Dr. Northrup remarked that in well-developed tubercular meningitis a gelatinous layer at the base of the brain was found usually, and it was very apt to be tinged with a green color. He had always regarded this condition as one of œdema of the pia with a small quantity of pus.

Dr. Van Gieson thought that the case ran a short course for one of tubercular meningitis. A gelatiniform exudation is not infrequently seen in such cases, and he was of the opinion that the quantity depended upon the intensity of the inflammation excited by the tubercular deposit. Chemically it was nothing more nor less than coagulated liquor sanguinis. He had not noticed the greenish tinge spoken of, but where there was marked congestion there had been, more frequently, the gelatiniform exudation.

With regard to the question whether or not syphilis may have been an etiological factor in the case, Dr. Van Gieson thought that in children it could be assumed with a great degree of certainty of being true, that syphilitic lesions of the skin will manifest themselves before cerebral symptoms develop, and as the skin in Dr. Knight's case showed no lesions, he should be inclined to eliminate the syphilitic element from the history; that view was also favored by the age of the patient.

Dr. Amidon asked if the temperature was not low for tubercular meningitis.

Dr. Van Gieson said he had seen quite a large number of cases of tubercular meningitis, and he had had one in which the disease ran its course, and terminated fatally, and the temperature at no time was above 100° F., taken in the rectum with corrected thermometers; the general manifestations of the disease were extremely characteristic. Whenever he was called to see a young child, complaining of headache, lassitude, loss of appetite, with grating of the teeth at night, etc., and a temperature of 99° F., he at once suspected, from the very fact that the temperature was low, that the life of the child was in danger, and that if there was to be a rise of temperature it was apt to be preagonistic.

Dr. Amidon regarded the temperature in Dr. Knight's case as belonging to syphilis rather than to meningitis, and fully believed that in ALL cases of meningitis, rise of temperature occurred before death.

Dr. Van Gieson believed that cases of tubercular meningitis occurred, not uncommonly, in which there were only slight exacerbations of temperature. In deciding the question of temperature, he regarded it as important that the thermometer should be introduced into the rectum, and allowed to remain for at least five minutes.

TUBERCULAR MENINGITIS.

Dr. R. W. Amidon presented microscopic slides with the following history: Female child, aged seventeen months. Maternal grandmother died of chronic pulmonary trouble, after the age of fifty years. Some of the grandmother's brothers died of phthisis when younger. Maternal aunt died recently of combined cardiac and pulmonary disease. Child's parents subject to colds.

The child had never been sick before. Was nursed by mother until over a year old. Was rather apt to take colds. Had a good deal of trouble with first few teeth. Had begun to walk alone, also talked some. Was a normally bright child.

About March 15, 1884, began to cut some back teeth, which seemed to cause much irritation. A week later became irritable, disinclined to play, and resumed creeping. Wouldn't walk, wanted to be let alone, and liked to lie down. All the time constipated. Ate well. About March 24th bored pillow a good deal. Four days ago was some irritation about right ear, which child rubbed a good deal. March 26th the left ear was likewise irritated. The child was treated for "teething," and had been given an unknown amount of hyoscyamine.

I was called to see the case at half past nine on the morning of April 5th. I then elicited the preceding history. I learned that after a good night's rest the child woke conscious, and immediately (7 A.M.) was seized with general convulsions, commencing with twitching of the face. Spells of clonic spasms of the face and extremities occurred at intervals from this time on. There was loss of consciousness, eyes open, fixed and to the right, was feverish before the convulsions. When first seen there was conjugate deviation to the right, eyes open and fixed, pupils dilated (hyoscyamia) and equal, slight occasional twitching about the left angle of the mouth and almost continuous slight twitchings in muscles of legs and fore-arms. Respiration, 60; pulse not perceptible at the wrist, because of tendinous twitchings; very hot and bathed in warm perspiration. 10.12 A.M.: temperature in left axilla, 41.5° C. (106° F.). 10.32: pulse, 120. 10.40: respiration, 34; temperature, 40.75° C.; began to give chloral hydrate hypodermically in .10 (two grains) doses, at intervals of ten minutes. This

seemed to check the convulsions. 10.55: pulse, 108; respiration, croupy and 36. 11.40: pulse, 80; respiration, 76; temperature, 40.75° C. Died about noon.

An autopsy revealed the pia of the base of the brain studded with miliary tubercules. Rest of the body not examined.

Dr. J. C. Peters had found the primary symptoms of tubercular meningitis more variable than of almost any other disease he had been called upon to treat. Some cases at the outset resembled remittent fever; in others there was merely a slight stiffening of the neck in the morning, which passed off in the afternoon; in some, projectile vomiting occurred without other symptoms, and as almost any of the nerves given off at the base of the brain were liable to be involved, a very great variety of symptoms could be established. He knew of no disease which presented difficulty in diagnosis for the first four or five days equal with that offered by tubercular meningits.

Dr. J. Lewis Smith thought the temperature depended upon the existence of meningitis. Tubercles might exist without meningitis, and without elevation of temperature, except, perhaps, a rise in the afternoon. If the meningitis was moderate, the febrile movement would be mild. He could coincide with Dr. Peters' remarks, and knew of no disease of childhood which was more difficult to diagnosticate at the beginning than tubercular meningitis.

AORTIC ANEURISM—ULCERATIVE ENDARTERITIS—AORTIC INSUFFICIENCY—CONGENITAL ANOMALIES OF THE LIVER.

Dr. Frank Ferguson presented specimens illustrating the above lesions removed from a male, fourteen years of age, and born in the United States. Only a few facts of the patient's history could be obtained. He did not give any rheumatic history. He had slight cough for some months. Two months previous to his admission into the New York Hospital on May 6, 1884, he complained of shortness of breath, weakness, loss of appetite, and he became pale and listless. On admission he was fairly nourished; there was no œdema of ankles and legs; face looked puffy; he was anæmic and cachectic. He was very dyspnoic and his respiration was largely diaphragmatic. His cardiac action was rapid and very irregular. The precordial area was increased; the apex-beat in the fifth space and nipple line. There was a harsh murmur, with the maximum of intensity at the apex of the heart, and heard with and after the first sound. In the third space, just to the left of the sternum, a soft bruit was heard with the first sound. The second sound was reduplicated. He quietly died two days after admission.

The *heart* is larger than normally found in subjects of this age; its cavities are dilated, and endocardium is thickened. There are vegetations on the segments of the aortic valve, some of them calcareous. One of the segments is almost entirely destroyed. Just above the attachment of the destroyed cusp there is a small round smooth opening in the wall of the aorta, communicating with a sac half an inch in diameter, with smooth walls situated in the upper and anterior part of the inter-ventricular septum.

Above this aneurismal sac there are several small irregular ulcers in the wall of the aorta, and one large ulcer, half an inch in diameter, with smooth bottom, and edges covered with vegetation.

The *liver* is ovoidal in shape, left lobe is rudimentary; there are three nodules of liver tissue on the under surface of the right lobe. The location of the gall-bladder is normal, but the fundus of the bladder is partially divided by a septum; the organ instead of being ovoidal or pyriform, is triangular in shape. The microscopic examination of the liver shows those changes which occur with cardiac valvular lesions.

The spleen was large, firm, and pigmented. The kidneys were larger than normal, firm and congested. The lungs were congested and pigmented—the condition of brown induration. The stomach was congested; also the mucous membrane of the intestines.

CHRONIC FIBROUS MYOCARDITIS.

Dr. George L. Peabody presented a heart removed from the body of a German woman, fifty-six years of age, who died in the New York Hospital, having been under observation about two weeks. The clinical history was meagre. The patient had borne several children, and had been in comparatively good health up to four months before her admission, except that without known cause she began to suffer from palpitation of the heart twelve years ago, and had suffered from it, at intervals, since that date. Four months ago she had an attack of pneumonia which ran a rather protracted course, but from which she recovered completely. She entered the hospital with dyspnœa, œdema of the lower extremities and lower half of the abdominal walls, and also with marked ascites. The chief subjective symptom was dyspnœa. When she entered, she was passing about the normal quantity of urine, but the quantity then diminished, and it contained albumen and hyaline and granular casts in abundance, and had a low specific gravity throughout. At the autopsy the kidneys presented the combined lesions of parenchymatous and interstitial nephritis, and the liver was found dislocated entirely below the free border of the ribs.

The chief interest centred in the condition of the heart, which contained a large amount of fibrous tissue, especially in the muscle about the apex, where the walls were very thin. Microscopic examination showed that, in the immediate neighborhood of the patches of distinctly fibrillated white fibrous tissue, there was distinct fatty degeneration of the muscular tissue, but beyond that the muscular wall was substantially normal. The endocardium was everywhere thickened, the attached borders of the aortic cusps were thickened, and there was atheroma in the aorta surrounding the opening of the coronary arteries, and also about the mitral valve.

Dr. Peabody remarked that he had not found fibrous myocarditis without atheroma in the coronary arteries.

There was a slight degree of cirrhosis and 2,500 cubic centimetres of fluid in the peritoneal cavity. Clinically, Dr. Peabody thought that this form of hypertrophy without valvular lesion gave the patient greater distress than any other.

Dr. Van Gieson asked Dr. Peabody if in such or similar cases he had observed symptoms of angina pectoris, as with calcification of the coronary arteries.

Dr. Peabody replied that he had seen two cases.

Dr. J. C. Peters had seen two specimens in which there was almost complete obstruction of the coronary arteries from atheroma, the patients having suffered from angina pectoris. Both patients died suddenly. In one there was rupture of the left ventricle.

Dr. Ferguson had had a case, within the last month, of large aneurism of the heart involving a part of the septum, and in which there was extensive interstitial myocarditis with some granulo-fatty change in the muscular fibre, but not distinct, and both coronary arteries had been almost completely obliterated by the lesion of endarteritis obliterans; there was no atheroma. The history of the case extended over eighteen months and the patient was seventy-six years of age.

Dr. Levi remarked that he had been taught that calcification and atheroma were two distinct conditions.

Dr. Peabody remarked that they did not necessarily pass into each other, but he thought that atheroma sometimes preceded calcification.

The Society then went into executive session.

A Munificent Gift.—St. George's Hospital, London, has recently received a bequest of $500,000 from the late Mr. William King.

THE PARIS ACADEMY OF MEDICINE.

Stated Meeting, June 10, 1884.

M. Alphonse Guérin, President, in the Chair.

(Special Report for The Medical Record.)

The Academy was called to order by the President, who announced the death of Mme. Richet, and expressed the sympathy of the members for M. Richet in his affliction.

M. A. Fournier presented a communication in behalf of M. Duclaux upon

THE MICROBE OF THE BISKRA BUTTON.

The coccus in question was obtained from the blood of a patient suffering from the Aleppo evil. It was found equally in the blood flowing from a puncture made in the immediate neighborhood of the boil, and in the general circulation. When introduced into the circulation of a rabbit there ensued a chronic disease, characterized by successive crops of boils, gangrenous at their apices, either scattered irregularly over the entire surface of the body, or grouped together, or sometimes even confluent. In general appearance they bore a close resemblance to the Biskra button. The rabbits, during this period of eruption, became thin and their fur was rough, though they continued to eat. After a while the boils disappeared and the animals recovered their usual health. In one case the eruption began ten days after the inoculation and continued a month.

Some further experiments were made with a view to determine the results of the

CULTIVATION OF THE COCCUS

in concentrated veal bouillon. The effects of the injection of the culture-fluid were found to vary according to the age of the cultivation and the mode of injection.

When injected under the skin in the dose of twenty drops, during the first days of the culture, extensive gangrene was caused. Later, when the fluid was about ten days old, the gangrene was of limited extent. Later still, localized phlegmons only were observed. And finally, two months or more after the commencement of the cultivation, the results obtained were negative.

When the fluid was injected directly into a vein death ensued at a period after the inoculation varying in length according to the age of the culture-fluid. After two months or more had elapsed, injection into the veins gave no results. But if a drop of this weakened culture-fluid were added to fresh bouillon, the evidence reappeared, becoming gradually less and less as in the first series of experiments.

M. Legouest remarked that the disease produced in the rabbit by these inoculations resembled in no way the Biskra button as seen in man. In the former case the eruption was said to have lasted a month, but in man the course of the Aleppo evil is of much longer duration. For this and other reasons he doubted whether it was the same disease in the two cases.

M. Blot inquired as to the number of times these experiments were repeated by M. Duclaux.

M. Fournier was unable to state positively, but did not doubt that they had been repeated a sufficient number of times. He was certain that the disease produced was really the Aleppo evil, and thought it not at all to be wondered at that its manifestations in the rabbit should differ from those in man.

M. Colin thought that the experiments, having been made on rabbits only, were by no means conclusive. If twenty drops of any kind of freshly prepared bouillon are injected into a rabbit, extensive gangrene and death by septicæmia may result. Later, when the animal matters of the fluid are destroyed by putrefaction, it may be injected with impunity. If now fresh bouillon is again used, whether a drop of the old fluid be added or not, we see the former series of results repeated. In order to be conclusive, the injections should be practised on larger animals, such as the horse or the ass.

M. Larrey agreed with M. Legouest that the disease described as having been produced in rabbits by inoculation with this coccus did not resemble at all the Aleppo evil as it occurs in man.

M. Bouley defended the author of the paper from the charge of having confounded the effects of septicæmia with those of the micrococcus of the Biskra button. Each animal reacts after its own fashion in the presence of a microbe, and it could not be expected that the symptoms of the disease in the rabbit should be the same as those met with in the human being. He thought the experiments of M. Duclaux were particularly interesting as showing how the microbe, having exhausted the nutritive elements in one solution, is able to regain new vigor when transplanted to a freshly prepared bouillon.

A memoir was then read by M. Du Mesnil, candidate for the title of Corresponding Member, on

CONCUSSION OF THE SPINAL CORD, SCLEROSIS OF THE LATERAL COLUMNS, AND DEGENERATION OF THE CELLS OF THE GRAY SUBSTANCE.

His conclusions were that: 1, Concussion of the spinal cord is a condition the existence of which, in the present state of science, ought to be maintained; 2, it may be the starting-point for secondary inflammatory lesions; 3, these inflammatory lesions may assume the form of circumscribed myelosclerosis.

M. Léon Labbé then read a paper entitled

INTRA-ARTICULAR IRRIGATION WITH CARBOLIZED WATER IN THE TREATMENT OF CHRONIC HYDRARTHROSIS.

After reviewing briefly the various attempts made to cure chronic hydrarthrosis by intra-articular injections of different substances, the author described the procedure known as Schède's operation. This consists in puncturing the articulation with a trocar of wide calibre, forcing out the fluid, and then injecting a three to five per cent. solution of phenic acid. A large quantity of the solution is used, and the injections are repeated until the water flows away perfectly clear. The wound made by the trocar is then sealed with gold-beaters' skin and collodion, the joint is enveloped in a thick layer of wadding, and the limb is immobilized in a guttered splint. Strict antiseptic precautions are observed, and the greatest care is taken to prevent the entrance of air into the articulation during the operation. The author had seen Schède perform this operation, and had himself operated upon two patients with success.

M. Jules Guérin regretted that M. Labbé, in his review of other modes of treatment, had not mentioned the one which had given in general the best results of any. This method, which he had employed for a period of thirty-five years, was divided into three parts, corresponding to the three stages of the disease. At the commencement of the disease, the treatment from which the best results are obtained is by vesication. Later, when the affection has lost in a measure its acute character, cold water is indicated. Finally, in the third and chronic stage, the treatment by means of

PUNCTATE CAUTERIZATIONS

is the one which is the most effectual in overcoming the disease. These cauterizations are a matter of every-day occurrence now, but it was far otherwise thirty or more years ago.

M. Colin claimed that the veterinary surgeons were the first to make use of the cautery in the treatment of joint diseases, and that the surgeons of to-day were merely imitators of the veterinarians in this respect.

M. Guérin said that punctate cauterization was a very different procedure from burning by hot irons as practised by veterinary surgeons. In the former case the burn was very superficial and never caused suppuration. Punctate cauterization, therefore, both in its mode of employment and in its effects, was essentially a new method.

The Academy then adjourned.

THE ROYAL IMPERIAL MEDICAL SOCIETY OF VIENNA.

Stated Meeting, May 30, 1884.

PROFESSOR LEIDESDORF, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society having been called to order by the President, DR. HOFMOKL exhibited some patients upon whom he had recently operated. The first case was one showing the results of

OSTEOTOMY OF THE FEMUR

for knock-knee. The operation was performed after Massini's method, and resulted in a perfect correction of the deformity.

The second patient had suffered for twelve years from symptoms of

VESICAL CALCULUS.

The median operation was performed, and an enormous stone was removed after crushing. It had nearly filled the bladder. It was composed chiefly of lime salts with a nucleus of uric acid. The patient was now well, except that he was unable to retain his water for any great length of time because of the paresis of the bladder, which still existed.

A third patient was shown, who suffered from

REPEATED BREAKING DOWN OF A CICATRIX.

A stone had been removed from his bladder by the high operation three years before. Since that time the cicatrix had yielded seven different times. There was no stricture of the urethra discoverable, though there was always considerable straining in passing water. When the cicatrix was about to break, it would be seen to swell out like a toy balloon, would then burst, and the urine would flow out through the anterior abdominal wall. These repeated occurrences had become almost unbearable, and the patient had already made one attempt to take his own life.

PROFESSOR V. DITTEL exhibited to the Society an apparatus, devised by Dr. Silbermann, of Breslau, for the

TEMPORARY CLOSURE OF ONE URETER.

It is a matter of great importance to the surgeon contemplating the removal of a kidney to determine whether the other is healthy and capable of secreting urine. It has hitherto been nearly impossible to determine this with any certainty owing to the difficulty of obtaining the urine of one kidney unmixed with the secretion of the other. The attempt has been made to catheterize the ureter, and has been successful in the case of women after dilatation of the urethra, but in man this is impossible. Dr. Silbermann's instrument consists of a catheter (No. 18 French) provided with a large opening $1\frac{5}{8}$ inches long, upon the side, and several small holes at its extremity. The instrument having been introduced, the eye being covered so as not to injure the walls of the urethra, a smaller canula is passed through. This small tube is provided with a rubber ball at its extremity, which, when in position, lies directly in the eye of the catheter. The instrument being so turned that this part lies against the mouth of the ureter, mercury is forced through the inner tube, dilating the rubber ball and effectually closing the orifice. Thus the urine that passes into the bladder can come from one ureter only, and a few minutes will suffice to show whether the corresponding kidney is performing its functions normally. The instrument has been tried several times in healthy individuals and has been found to answer the purpose intended.

PROFESSOR MAUTHNER then exhibited a patient with

OPHTHALMOPLEGIA INTERIOR,

or paralysis of the muscle of accommodation and sphincter iridis, with preservation of function of the external muscles of the eye. After the reading of a paper on

CEPHALOMETRY AND CRANIOMETRY

by PROFESSOR BENEDIKT, the Society adjourned.

THE BERLIN SOCIETY OF INTERNAL MEDICINE.

Stated Meeting, May 26, 1884.

HERR LEYDEN, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE first paper of the evening was read by HERR G. BEHREND upon the

NATURE OF PRURIGO.

The author took exception to the teaching of the Vienna school that skin diseases are essentially local affections, and maintained that they may arise from changes in the blood, or may be symptoms of some general disease. In proof of this position he cited the eruptions that are often seen to follow the long-continued use of certain drugs, and those occurring in nephritis, or in the exanthematous diseases. These eruptions, he stated, are independent of the nature and specific action of the matters under whose influence they arise. Hence they may be called, and were so called by the author himself, in his work on dermatology,

HÆMATOGENETIC ERUPTIONS OF THE SKIN.

No direct evidences of the hæmatogenetic origin of prurigo have hitherto been forthcoming, but the speaker had recently observed two cases which seemed to supply the omission.

The first was that of a child, seven and a half years of age, who had had scarlatina some two years and a half ago. It had previously been a healthy child with a complexion free from any appearance of eruption. Just as the desquamatory stage was at an end there was a thick eruption of pustules, most noticeable on the lower extremities, but present also on the body and arms. As these pustules dried a new crop appeared, and then another, and another for some eight or ten weeks. When this pustular eruption ceased a prurigo appeared, and still existed at the time of the report. The eruption occupied the extensor surfaces of the articulations chiefly, and was entirely absent from the flexor surfaces. There was also some pigmentation of the skin, and swelling of the inguinal glands.

The second case was a seven-year-old boy, who had had scarlet fever and secondary nephritis three years previously. When first seen some months after the subsidence of the original disease, he was suffering from well-marked and typical prurigo. The mother stated that a pustular eruption was first seen, which gradually disappeared and gave place to the prurigo.

The speaker maintained that the scarlatinal poison had first given occasion to the development of the prurigo, though the latter had remained after the cause had been removed from the system. A similar occurrence is seen in the persistence of an eczema, following vaccination, long after the influence of the vaccine virus upon the organism has ceased.

HERR LEWINSKI thought the prurigo was due to the inflammation of the skin accompanying scarlatina rather than to the scarlatinal poison.

HERR BEHREND rejected this view and maintained that the localization of the eruption upon the extensor surfaces of the joints, as well as the pigmentation of the skin, were sufficient to establish the correctness of his diagnosis. He regarded the pustular eruption as the transition stage between scarlatina and prurigo.

HERR KRONECKER presented an account of some experiments made by himself and Herr Schmey, in the course of which they had accidentally discovered the

CENTRE OF CO-ORDINATION FOR THE VENTRICULAR PULSATIONS.

The experiments were being conducted with a view of establishing the mode of contraction of the ventricles. A dog was put under the influence of curare, artificial respiration being maintained while the heart was exposed and raised up to the opening in the thorax. The reg-

istering apparatus being ready, Herr Kronecker thrust a needle into the heart in order to record its movements. At that instant the ventricles ceased pulsating, dilated, and presented only irregular fibrillary twitchings. The needle was removed at once and the heart was kneaded, but without avail. The auricles continued to pulsate, but the animal died without a single beat of the ventricles occurring. This accident led to further investigations, in which the experimenters found that an injury to the cardiac wall at a certain point invariably caused paralysis of the ventricles. This point, the limits of which were not yet exactly mapped out, was over the lower boundary of the upper third of the ventricular septum near the descending branch of the left coronary artery. Here, then, must be the distributing point for the nerve-supply, the part where the messages to the different muscular fibres are arranged and co-ordinated, so that each portion of the ventricular wall shall contract in harmony with every other portion. When this centre is destroyed the separate muscular bundles do not contract with less force but irregularly.

Experiments were also made to determine the effects of irritation upon this newly-discovered co-ordinating centre. It was found that a very weak induced current passed through this point was sufficient to arrest the rhythmic pulsations of the ventricle. But if the electrodes were placed at a distance from this centre it required a current of much greater strength to produce the same effect. Herr Kronecker thought that the cases of sudden death from

PARALYSIS OF THE HEART

were to be explained through this excessive vulnerability of the co-ordinating centre In sclerosis of the coronary arteries, fatty degeneration, and sometimes during convalescence from acute diseases, sudden death from paralysis of the heart has been observed. In such cases the individual may breathe several times after the cardiac pulsations are no longer perceptible. It is fortunate that this centre is situated in a part of the ventricular wall so well protected from external injuries.

In concluding, the speaker reminded his hearers that these experiments were made upon dogs only, and it was very probable that the centre of co-ordination in the animals of a lower order was not so strictly defined. This should be borne in mind if similar experiments were made on rabbits or frogs, otherwise the results obtained might appear to conflict with his own.

The Society then adjourned.

A Criticism from India on the Cholera Bacillus.—The *Indian Medical Gazette*, in the course of an elaborate review of Koch's work and discovery, says: "A review of the whole evidence brought forward by the German Cholera Commission shows that they have only succeeded in establishing the fact that a peculiar form of bacillus is normal to the intestines of cholera patients; but the exact part which this organism plays in the morbid process is left wholly undetermined. Only a very moderate degree of probability has been made out in favor of this bacillus being the cause of cholera; but the futility of trusting to probabilities and conjecture in an etiological inquiry into cholera is generally well recognized. The problem, therefore, of the causation of cholera still remaining unsolved, it awaits and ought to receive that careful attention which its great importance demands." It is not fair to depreciate the value of Koch's discovery; but, on the other hand, it will do no good to give to it any greater weight than the evidence strictly justifies.

The Number of the Blind in Russia is unusually great, amounting in some districts to .2 per cent. of the population.

THE THERAPEUTICAL SOCIETY OF PARIS.

Stated Meeting, May 28, 1884.

M. Delpech, President, in the Chair.

(Special Report for The Medical Record.)

After the Society had been called to order, M. Petit exhibited some specimens of

EUPHORBIA PILULIFERA.

This plant, which resembles the ordinary wartwort (*réveille-matin*), grows in stony places in the neighborhood of Brisbane, Australia. It is used in that country and in England in asthma and all chronic spasmodic bronchial affections. An infusion is made of one ounce of the fresh plant in three and a half pints of water, of which the dose is a glassful morning and evening. M. Petit offered to furnish samples of the dried plant to any of the members who might desire to experiment with it.

M. E. Labbé continued some remarks which he had made at the previous meeting upon the properties of

OZONIFACIENT WATER.

This product, which may be extracted from the *pinus maritima*, was discovered by M. Boursier, and is really a

TEREBINTHINE HYDRATE.

Its ozonifacient properties give to it a special value as a disinfectant. It may be used in the form of spray, vapor, or as a liquid. If the spray be directed over any putrefying and foul-smelling material the fetid odor is at once destroyed. The vapor possesses a terebinthinate odor, and would seem to be indicated in the case of fetid expectoration. The vapor is certainly absorbed by the respiratory mucous membrane, for when inhaled for any length of time symptoms of intoxication are produced. In the

TREATMENT OF DIPHTHERIA

a wash of ozonifacient water has appeared to give good results, but the trials of the remedy in this disease have been too few to allow of any definite conclusions. Compresses wet with the substance and applied to any surface giving off a fetid secretion are productive of good results. The speaker thought that this product, owing to its cheapness and the small quantities which it is necessary to employ, was destined to assume the first rank among the disinfectants.

M. Blondeau remarked upon the strong terebinthinate odor of the substance, and suggested that it owed its disinfectant properties to the turpentine which it contained.

M. Labbé maintained that turpentine had no such ozone-producing properties as the product in question was shown to possess.

M. Dujardin-Beaumetz exhibited some fresh and dried specimens of the

KOLA NUT,

the fruit of the *sterculia acuminata*, a tree growing in Central Africa. The natives look upon it as a universal cure-all, and attribute to it tonic, nutritive, excitant, and aphrodisiac properties. Analysis shows that kola contains caffeine and tannin in large proportions and a relatively less amount of theobromine. It has been used with success in the diarrhœas of hot climates, in cardiac diseases, and as a tonic.

M. Petit asked whether the beneficial effects of the kola nut were not due to the caffeine contained in it, and thought, if this were so, it would be much better to use the latter drug by itself than to give it mixed with other inert substances in the form of kola preparations.

M. Dujardin-Beaumetz then made a few remarks upon

HAMAMELIS VIRGINIANA.

He said that, while not agreeing with those who thought no substance could possess valuable therapeutic properties which was not poisonous in large doses, he must

nevertheless say that he had never been able to observe even any physiological effects from witch-hazel.

M. Campardon related two instances in which he had observed a gradual

DECOLORATION OF PIGMENTED SPOTS,

due to varicose veins, following the internal administration of an infusion of hamamelis. In neither case was the remedy applied locally.

After some further remarks by the members regarding the parts of the plant in which the active principle was contained, the Society adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SIR JAMES PAGET'S ADDRESS AT THE HEALTH EXHIBITION—THE CONSERVATORSHIP OF THE COLLEGE OF SURGEONS—BURIAL ALIVE—OVERPRESSURE IN SCHOOLS—STATE OF THE THAMES—SMALL-POX IN LONDON—CONFERENCE ON SANITARY LEGISLATION.

London, June 21, 1884.

On Tuesday last, June 17th, the Prince of Wales paid his first visit to the International Health Exhibition, and on this occasion an address was delivered by Sir James Paget in his usual felicitous manner. Sir James deprecated mere comfortable idle health. The pattern healthy man was, he said, one who lived long and vigorously; who in every part of his life did the largest amount he could of the best work, and when he died, left healthy offspring.

Referring to published statistics, Sir James Paget pointed out some striking facts. He estimated that in this country the whole population between fifteen and sixty-five years of age do, in each year, twenty million weeks' less work owing to sickness. He remarked that typhoid fever alone destroyed 4,000 working people a year in England and Wales. From this one preventable disease we had an annual loss of 230,000 weeks' work from illness. Referring to infantile mortality Sir James remarked that in 1882 the mortality of children under fifteen was nearly a quarter of a million. If you reckoned that each child cost only £8, more than two million pounds sterling were thus lost every year. But they had cost much more, and much more still was lost by the loss of the work they might have lived to do. The numerous diseases that might be prevented by suitable precautions were then referred to, and Sir James Paget concluded by urging that we wanted more ambition for renown in health. He would like to see a personal ambition for renown in health as keen as that for bravery, or for beauty, or for success in our athletic games and field sports; as for national renown in war, or in arts or commerce.

Mr. Stewart, of St. Thomas' Hospital, has been elected to the Conservatorship of the College of Surgeons, vacant through the resignation of Professor Flower, who was appointed to the Natural History Museum some months since.

A controversy has been going on lately in the columns of *The Lancet* as to the possibility of persons being buried alive. Some of the correspondents deny the possibility of this occurrence altogether. Some of the facts narrated by others seem to show that it has occurred even in the present century. It is very pertinently pointed out that burial should not be permitted till some signs of decomposition have appeared. A good deal of discussion took place some years ago as to various "signs of death," but no more reliable sign, and one of such easy application, has as yet been pointed out.

Overpressure in education is again denounced by sanitary authorities. The system of payment by results seems partly to blame in Board Schools. This makes it the direct interest of the teachers to force as many pupils as possible up to a given standard, and tends to press hardly on the weaker or duller members of a class. But overwork is not confined to Board Schools, nor to students of tender age. Every now and then we hear of suicides among university and other students attributed to overwork for competitive and other examinations.

The condition of the Thames during the last week is presumably due to the unusual dryness of the season. Between Twickenham and Kew the bed of the river has been exposed at low water, and children have actually crossed on foot from one side to the other. The river is said to be getting shallower day by day. Should this prove to be the case, the intra-metropolitan portion of the stream can scarcely fail to be affected. The stagnation of sewage at Barking and Crossness will probably become more offensive, and other dangers to health are likely to ensue.

Small-pox is still on the increase in London. Last week (ending June 14th) the number of patients under treatment in the hospitals, hospital-ships, and convalescent camp of the Metropolitan Asylums Board rose to 1,238, being an increase of 142 on the preceding week. The number of new cases admitted during the week was 332. Owing to the further increase in the number of patients under treatment, it has been found necessary to lease a hospital belonging to the Poplar Board of Works. It is cheering to note that the deaths from small-pox in London during the same week were only 30 in number.

A Conference on sanitary legislation will be held next week at the Health Exhibition. It will last two days, and be under the auspices of the Social Science Association.

OUR PARIS LETTER.

(From our Special Correspondent.)

REMOVAL OF CONTAGIOUS DISEASES TO HOSPITALS—HOW IT IS DONE IN PARIS—THE NEW METHOD FOR THE TRANSFUSION OF BLOOD—A CURIOUS CASE OF MALINGERING—HOW A THERMOMETER WAS TAMPERED WITH.

Paris, June 20, 1884.

A very useful measure has been taken by the Prefect of police with reference to the removal of persons suffering from contagious diseases to the hospitals from their own homes. Special carriages have been constructed for the purpose which are kept at the Hôtel Dieu, and he has informed the commissaries of police of each district that all that will be required is a medical certificate as to the nature of the malady of the applicant, giving his name and address. These carriages are placed at the disposal of the public daily from 8 A.M. to 6 P.M., and in order to get one application must be made to the commissary of police of the quarter in which the patient resides, or to the central police office of the district. No charge will be made for the use of these carriages, and the commissaries of police are further instructed thoroughly to disinfect the carriages after each journey, and also to disinfect the room from which the patient has been removed. Hitherto these carriages were reserved for small-pox patients only, but they are now to be available for all contagious or epidemic maladies, such as small-pox, scarlet fever, measles, diphtheria, etc. This, as I have said, is certainly a very useful measure, but unless the public are made acquainted with such an arrangement in a more efficient manner these carriages will scarcely ever be called into requisition, as has happened with the ambulance-carriage reserved for small-pox patients, as the public being ignorant of its existence for the last two years, it is reported that it was taken advantage of only ten times during that period.

At a recent meeting of the Academy of Sciences Professor Vulpian read a paper for M. Afanassiew, a Russian physiologist, on a new method for the transfusion of blood, which consists of peptonizing the latter, by which means its coagulability is suppressed for a certain time.

M. Afanassiew acquired the knowledge of this fact by experiments he had performed on dogs, from which he removed two-thirds of their blood, which reduced them to death's door. In injecting into their veins blood mixed with peptones, he was enabled to restore them to life. According to the author these peptones do not in any way affect the globular elements of the blood; the peptones simply prevent coagulation, and thus render useless the process of defibrination before injecting the blood. M. Afanassiew promises to continue his experiments on animals before venturing to apply his new method to man.

A very curious case of malingering was recently brought to the notice of the Société Médicale des Hôpitaux by Dr. Du Castel, which was detected in a young woman in a hospital under the following circumstances: She was admitted for a herpetic disease of the throat, and in going into her previous history she stated that she had had an attack of pneumonia, which, however, was considered doubtful, as she had recently had an attack of hæmoptysis. She had never had convulsions. At the end of five or six days, the sore throat was almost completely cured, and the temperature of her body, which had risen to 39.5° C., fell to nearly normal; but she was seized with an attack of delirium followed by great excitement which lasted several hours. A few days later, the patient declared that she had spit up a good deal of "thick matter" during the night, which nobody saw, as she had emptied her spittoon before the doctor's visit. Soon after this, she presented symptoms of coma, accompanied with a slight increase of the temperature. This was followed by complete paraplegia accompanied with generalized hyperæsthesia. Finally followed a series of hysteriform attacks, distinctly marked aphasia, mutism, etc., the thermometer ranging at this time from 39° C. to 39.5° C. The physician hesitated in his diagnosis of hysteria, and he felt inclined to ask himself whether, owing to the deafness which existed during the attack of sore throat followed by spitting up of matter (?), there was not some lesion of the internal ear complicated with cerebral abscess. This state of uncertainty lasted some time, when one morning the interne charged to take the temperature of the patient observed to his surprise that the thermometer marked 43.4° C. It was imagined that there might have been some error, and the temperature was again taken, when the thermometer marked 39°. Eight days later the thermometer marked 43° and a few tenths, then the temperature remained for a few days after about 39°. One morning the thermometer marked 44°. This naturally puzzled the interne and the physician, when it was resolved to examine all the thermometers of the ward, but nothing wrong was detected; nevertheless the temperature as taken each day was sometimes 38°, sometimes 43°, and sometimes 39° C., but the rise or fall was the same whether the thermometer was applied to the axilla or in the vagina, and the thermometer had even risen to 48°. Suspecting some trickery on the part of the patient, she was closely watched, and as it appeared to the physician that as the patient got the mercury to rise so high he saw no reason why she should not succeed in getting it to rise even higher, and as the ordinary clinical thermometer was not long enough, he used a stove thermometer marking as high as 160° Centigrade, and to his great confusion, and that of his assistants, this thermometer, which was placed in the axilla, one morning marked 76°, which a few days later was even surpassed. The trickery was, however, at last found out. When the patient thought she was not observed, she was seen approaching her left hand to the lower extremity of the thermometer which was placed in the right axilla, and finally the mystery was discovered. The interne, who was on the watch, demonstrated that by gently and repeatedly striking the lower extremity of the thermometer, the mercury could be made to rise to any height in the instrument. Dr. Du Castel, who communicated this case to the Medical Society, said he merely wished to observe of how little use it was to take the temperature in hysterical patients unless they were closely watched.

Dr. Hanriot Agrégé has been appointed Professor of Chemistry at the Paris Faculty of Medicine, in the room of Professor Wurtz, lately deceased.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 29 to July 5, 1884.

GIRARD, J. B., Captain and Assistant Surgeon. Ordered to relieve Surgeon W. E. Waters from duty as Post Surgeon, Plattsburg Barracks, Plattsburg, N. Y. Surgeon Waters, upon being relieved, directed to return to his proper station (Madison Barracks, N. Y.). S. O. 131, par. 3, Headquarters Department of the East, June 30, 1884.

HARTSUFF, ALBERT, Major and Surgeon (Fort Riley, Kan.). Granted leave of absence for one month, with permission to apply for one month's extension. To take effect when his service can be spared. S. O. 130, par. 6, Headquarters Department of Missouri, June 25, 1884.

MIDDLETON, J. V. D., Major and Surgeon. Ordered to relieve Surgeon B. E. Fryer from duty as Post Surgeon, Fort Leavenworth, Kan., on or before July 1st. S. O. 133, par. 5, Headquarters Department of Missouri, June 28, 1884.

BENHAM, R. B., First Lieutenant and Assistant Surgeon. From Department of Dakota to Department of Texas. S. O. 150, par. 8, A. G. O., June 28, 1884.

GORGAS, WILLIAM C., First Lieutenant and Assistant Surgeon. From Department of Texas to Department of Dakota. S. O. 150, par. 8, A. G. O., June 28, 1884.

WALES, PHILIP G., First Lieutenant and Assistant Surgeon. From Old Fort Colville, Washington Territory to Fort Cœur d'Alene, Idaho. S. O. 89, par. 3, Headquarters Department of Columbia, June 23, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending July 5, 1884.

WELLS, H. M., Surgeon. Detached from Naval Hospital, Brooklyn, ordered to U. S. S. Lancaster.

SAYRE, J. S., appointed Assistant Surgeon. Commission dated June 27, 1884.

CORDEIRO, F. J. B., appointed Assistant Surgeon. Commission dated June 27, 1884.

PREVENTION OF CHOLERA.

[1884. Department No. 98. Marine Hospital Service.]

TREASURY DEPARTMENT,
OFFICE OF THE SECRETARY,
WASHINGTON, D. C., July 2, 1884.

To Collectors of Customs:

It has been brought to the attention of the Department that persons from the infected districts of France are leaving in considerable numbers by other than French lines. You will, therefore, require evidence that none of the baggage of immigrants or returning travellers has been shipped from the infected districts since June 20, 1884. A certificate of the local quarantine officer to the effect that no danger to the public health need be apprehended from allowing the landing of any passenger's baggage, may be accepted as entitling such traveller or immigrant to land his effects.

CHAS. J. FOLGER,
Secretary.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 5, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
June 28, 1884	5	16	56	6	186	35	0	0
July 5, 1884	3	6	27	3	156	41	0	0
Deaths.								
June 28, 1884	2	5	17	5	29	15	0	0
July 5, 1884	0	2	12	3	30	20	0	0

THE SIGNIFICANCE OF SCARS AND COPPER-COLORED SPOTS ON THE FOREHEAD.—T. Pershing, of Wilmington, Del., criticises a statement made by Dr. A. L. Ranney in the first of his articles on "Methods of Examination in the Diagnosis of Nervous Diseases," published in THE RECORD. It is there affirmed that ulcerations upon the forehead not traumatic are syphilitic; scars and copper-colored spots are equally significant. Dr. Pershing says that "herpes zoster occurring on the forehead may be severe enough to cause ulcerations."

THE TREATMENT OF ASPHYXIA.—A lecture was recently delivered by Dr. Benjamin Howard, in the course of Professor Charcot, at the Salpêtrière, upon the mechanism and treatment of asphyxia. The plan usually followed, of making traction upon the tongue, is, the lecturer stated, useless, for the anatomical conditions will not admit of elevation of the epiglottis by this means. The only way by which this elevation can be accomplished is to place the head and neck in a position of forced extension. When this is done, the tongue is separated from the pharynx and a wide and free passage without any obstruction is established leading directly from the posterior nares to the lungs. The lecture was supplemented by demonstrations upon the cadaver in which the facts were proven to be as stated.

DERMATOLOGY AT VIENNA.—A correspondent of the *Northwestern Lancet* writes: "One very noticeable feature is the almost exclusively local treatment of all skin diseases, except those due to syphilis, and the scrofulous or tuberculous diathesis. Though Kaposi mentions iron and arsenic in his book, I never saw it given or mentioned in the hospital. Scrofulous and chlorotic patients were given cod-liver oil, which was almost the only internal medication which I observed. He says the internal treatment of skin diseases was proven useless years ago in this hospital. He is accustomed also to occasionally express himself very strongly upon the doctrine that tubercle, lupus, and syphilis are related diseases. He, as well as Neumann, repudiates this idea in toto. On every reference to the subject he says: 'Gentlemen, lupus is lupus, tubercle is tubercle, and syphilis is syphilis. Any shading of the one into the other does not exist. Syphilitic lupus is nonsense.' Lately he read that Koch claims to have discovered the tubercle bacillus in lupus nodules. He said on coming to the class: 'Gentlemen, if this be so, all I have to say is that it is bad for the bacillus, for it would be proof positive that he is not the cause of specific tuberculosis.' The favorite treatment of lupus is removal of the nodules with the caustic potash stick or a curette, and application of mercurial plaster. During the winter he used the treatment of the sublimate solution. It bleached the ugly-looking surfaces, removing the coloring matter from the scars very nicely, but caused so much eczema, and the apparent benefit was so transient that it was soon thrown aside. Psoriasis, when not covering too great an area of skin, is treated by removing the scales with a curette, or, after maceration with soft soap, removal in the bath with a scrubbing brush; after which the affected parts of the skin are painted with chrysarobin salve—chrysarobin 5 or 10 to vaseline 40—twice a day for several days. Every one of the large number of cases which I observed improved rapidly. Owing to the discoloration of the skin caused by chrysarobin, the face, head, and hands are never treated with this remedy. On these parts tar is still the favorite. A pyrogallic acid salve of the same strength is sometimes used, spread upon linen, and after removing the scales as before. It does not cure so rapidly as the chrysarobin, but in skins which would be too severely inflamed by the latter drug it proves very useful."

THE TREATMENT OF TAPE-WORM — TAPE-WORMS AND PREGNANCY.—Dr. Frank H. Rowe, of Cumminsville, O., referring to a request for opinions regarding the treatment of tape-worm, sends the following. The ingredients must be reliable and the compounding carefully done: "℞. Pulv. cort. radix granat., ℥ ss.; pulv. secale cornut., ʒ ss.; pulv. gum acacia, ʒ ij.; ol. felicis, ʒ j., ol. crotonis, one drop, mixed well; mix well in rotation, pulv. peponis, ℥ j. M. Ft. emulsio with aq. dest., ℥ vij., add sodæ salicylate, grs. xv. S. Take the above emulsion at once in the morning. One hour before taking it, take a small cup of good coffee alone; the emulsion should be taken while lying down, a sinapism of pure mustard having been previously applied over the epigastrium. *After* the free use of saline cathartics, sol. magnes. cit., ℥ xij., magnes. sulph., ℥ j. M. S. at once —to be taken the *previous* day. And the evening before taking the emulsion, the supper should consist of a very liberal repast, consisting exclusively of onions and herring (or mackerel) salad. While referring to the subject of tape-worm, I would notice a recent article in the *London Record* in relation to the reflex disturbances produced by tænia, ascribing a series of miscarriages in one or two individuals to their presence, pregnancy going on to full time after the removal of the worm. Such has not been my experience in a recent case of a similar character. A patient having had at least four miscarriages between the fifth and seventh month, accidentally discovered evidences of the presence of a tape-worm. I successfully treated her for it in the meantime. She became pregnant, and flattered herself that the cause of her miscarriages was removed, and that she would go on to full time. Such, however, was not the case, as at the usual time she miscarried. Habit possibly had some influence in determining this. The reflex disturbances produced by tænia seem to be over-estimated. And, judging from the physical condition of cases seen, one must conclude that their effect upon the health of the individual containing them must oftentimes be almost *nil*."

ANTIPYRIN is the name of a chinolin-derivative, first used by Filehne and recently experimented with by P. Guttmann. In doses of two grammes it reduces the temperature powerfully, this reduction lasting five to six hours. It has no bad after-effects, and only very rarely disturbs the stomach.

A NOVEL METHOD OF CULTIVATING BACILLI.—Prof. Baumgarten takes a bit of tuberculous tissue and introduces it with antiseptic precautions into the anterior chamber of a rabbit's eye. After six or eight days he removes a small portion of the tuberculous nodule and introduces it into a second rabbit's eye, and in six to eight days repeats the process with a third rabbit. He thus gets a mass of tubercle bacilli almost entirely free from extraneous tissue. He recommends this method as the most convenient and certain way of securing pure cultivations.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 26, No. 3 NEW YORK, JULY 19, 1884 Whole No. 715

Original Articles.

SOME REMARKS ON AFFECTIONS OF THE HEART.

By J. MILNER FOTHERGILL, M.D. EDIN., HON. M.D. RUSH MED. COLL., ILL.

ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

III.

STRUCTURAL CHANGES.

PROBABLY there is no disease to which humanity is liable more dreaded than fatty degeneration of the heart. All students are liable to have this weird malady, wrapt in mystery, when first studying disease of the heart; it is the *bête noir* of many persons who curiously dip into medical literature, especially if their thoughts are directed by their family history to cardiac maladies; perhaps medical men themselves fear it more than any occult malady with the exception of aneurism. Why is all this? Because it is a general belief that fatty degeneration of the heart is a disease which is shrouded from our ken; it stalks in darkness, unseen, beyond detection. Mystery gives it its terrors; it belongs to the unknown! Nothing of the kind! It is a malady which reveals itself, albeit not one which forces itself upon the attention like valvular disease, or a paralyzed limb. Fatty degeneration of the heart has its known history, its pathological relations, like other diseases. That it is the cause of sudden death may at once be laid down as an axiom. So long as its structure is unimpaired, its muscular fibrillæ sound, the heart will struggle on, often though the cause of death, yet itself the last to die.

Fatty decay of the heart-wall may go on masked by other troubles, and, consequently, not be recognized, as occurred in a patient of mine at the hospital while writing these papers. She was a woman in the fifties, with some œdema in her legs, and a mitral lesion; not, apparently, a very serious case. She stood a full dose of compound jalap powder without any suspicious indications, and seemed to be improving, when suddenly she died without a struggle. When the post-mortem came the explanation was not far to seek. She had a nutmeg liver, granular kidneys, and the texture of the heart-wall was considerably impaired. She had been, in all probability, a drunkard. But of this it is impossible to be certain. A faint arcus senilis and a cloudy cornea was the only outward visible sign of the inward pathological changes. Here fatty degeneration might have been suspected, but it was certainly not palpable. There was no clot in the heart: death had come about by fatal syncope. And it is this last to which fatty degeneration renders its victim liable; no matter whether the appearance of general health is maintained, or, as in the case just given, there is also other palpable disease present.

At other times an elderly man dies suddenly after an effort, as rushing to catch a train; or after emotion, like the great anatomist John Hunter; or at some gathering; or on the night-stool, as died a well-known temperance lecturer under my own care not long ago. In the last case a hale, well-nourished, florid, elderly man, who had quite recently been lecturing with his wonted vigor, was seized with an attack of severe dyspnœa, which left him shaken, but not otherwise the worse of it. His medical attendant called me in in consultation, and the circumstances roused my suspicions that the right ventricle was not to be trusted. Strict orders were given about quiet being maintained, all effort avoided, especially straining at stool (which brought on the attack), and no lectures to be announced for some time. All went well for a time, and he began to think the doctors took too grave a view of his case. So he went down to the city to see to some business, came home, after that went into the water-closet, and died there. There is no moral doubt that there was fatty decay of the right ventricle present in that case.

What are the indications of a fatty decay in the heart-walls? The heart has a dead-leaf here instead of the normal dark flesh color, *i.e.*, when the condition is pronounced; it is friable, readily torn, and if a piece be pressed between blotting-paper the stain of grease is found. Under the microscope, first, the transverse striæ are clouded and then lost; second, granules of fat are to be seen near the germinal matter, afterward spreading throughout the fibril; third, the fibril has given way to a string of oil globules within the sarcolemma. The disease may be general; it may be connected with the area supplied by one coronary artery; or it may belong only to the area fed by one branch of one of the coronary arteries, where that branch is occluded by some growth in the wall of the vessel.

What is the cause of decay in the fibrillæ of the heart-wall? An insufficient supply of blood. How is that brought about? By an atheromatous condition of the tunica intima of the nutrient artery usually. Degenerative change in the coronary vessels is the cause, *par excellence*, of fatty necrosis of the muscular fibrillæ of the heart. There may be an atheromatous tubercle blocking the orifice of a coronary artery, as was found in an elderly gentleman who died in the sexual act with a venal Venus, in one of our London parks, some time ago. Or it may be that an adherent pericardium along the coronary vessels cuts down the blood-supply until the heart-fibre is no longer properly nourished, as was said to be the case with the late renowned Sir James Young Simpson. But, speaking broadly, when fatty degeneration of the heart-wall is found, the coronary arteries are the seat of atheromatous change. Atheroma is the development of connective corpuscles in or under the tunica intima of the arterial wall. It may be in patches or it may be diffused. Usually there is the hard artery, liable to be also tortuous. The change can often be seen in the temporal arteries, which to the eye elongate on each pulse-beat. The artery loses its elasticity while its lumen is diminished.

The general associations of the fatty heart are these: First, the "gouty heart," or chronic Bright's disease, a large left ventricle, a tight artery, and an accentuated second sound at the aortic root. The physiological evidence of high arterial tension is a large bulk of urine. But after a time the bulk of urine drops; and as Sir William Jenner has pointed out, this is a clinical fact of the grimmest significance. Why is the bulk of urine falling? Because the hypertrophied heart-wall is being undermined by a decay in the muscular fibrillæ. There are other evidences of a waning energy in the left ventricle, and the case either ends suddenly, or presents the well-known features of heart-failure. Sometimes there is little hypertrophy, and these are, apparently, the cases where death takes place suddenly, on or *after* some effort, as a rule. Old people are intensely reticent when they have done something foolish, and if all the circumstances could be known, my

own individual opinion is that a history of some effort would be found to precede the fatal syncope in almost all cases where the heart ceases suddenly in diastole in persons apparently well. In some cases the fatal event occurs in a person apparently in fair health, as in the case given of the temperance lecturer. At other times evidences have been furnished of failure of the heart unmistakably pointing to the morbid change. At other times men are seen with a tranquil gait, very careful of themselves, apt to have attacks of vertigo, are seen at times to clutch at some object to help them to keep up, who are said to be the subjects of fatty degeneration of the heart—and doubtless in some cases this is correct. At other times such is not the case. I remember when in general practice being called in to see an old gentleman, who from his evidences of failing strength, plus the feebleness of his heart-sounds and the condition of his arteries, was to all appearance the subject of a fatty heart. Yet by rest and tonics in time he improved greatly, and as the heart regained its tone an aortic systolic murmur could be heard while there were evidences of hypertrophy of the left ventricle. When I left the neighborhood he was a hale, fairly active old man, and died of something unconnected with his heart. It is quite clear that this case was not one of fatty degeneration of the heart, but rather one of temporary malnutrition.

How is it that very often the morbid condition of atheromatous change is more pronounced in the coronary arteries than in any other part or portion of the arterial system? Such is undoubtedly the fact, and the thickened, tortuous, white coronary arteries stand out prominently by contrast with the blue veins when the heart is laid bare. They are thickened, and what is more, their calibre is diminished, and with that the blood-current which flows through them. The heart-muscle is underfed, and then, in time, fatty degeneration of the fibrillæ follows. Why is the coronary circulation so much more than any other part of the arterial system the seat of this morbid process? To my mind, the answer is, that this is due to the fact that the coronary arteries spring from the aortic root and so are filled by the full force of the aortic recoil. Other arteries of *like* size have the shock broken by intervening moderate sized vessels, or are not so forcibly dilated by the aortic recoil. The full force of the aortic recoil falls upon the aortic valves, and the blood-current eddies furiously in the sinuses of Valsalva, acutely distending the coronary arteries. Especially is this the case with the hypertrophied ventricle and high arterial tension of the gouty heart. Atheroma is the result of over-distention (*ueberspannung*) plus some tissue-tendencies of the gouty diathesis, or the syphilitic cachexia. Consequently, while the aorta and the rest of the arterial system are but in an early stage of the atheromatous change, and still possess considerable elasticity, the coronary arteries are in an advanced condition, are tortuous, inelastic, with their calibre gravely diminished by thickening of the tunica intima encroaching on the bore of the blood-vessel. The lessened blood-current is broken in its course by the curves of the artery and an insufficient blood-supply to the heart-muscle leads to its decay. Such is, to my mind, the sequence of the events.

Consequently fatty degeneration is the sequel to the gouty heart. Such at least are its clinical phenomena as presented to me in my experience. Of course a man must be guided by what he himself has seen and encountered; he cannot be so familiar with the experience of others, but what I read of their observations tallies with my own. As an apple waxes, ripens, and ultimately rots, so the gouty heart passes through these varying phases of muscular growth, high arterial tension, hardening arteries, and diminution of calibre by the atheromatous change, the blood-supply to the cardiac muscle being cut down until the muscle is unequal to its work, and stops in diastole. Having run the risks of the heart bursting the arteries, the big heart gradually rots and stops. Having passed the rocks of the earlier risks the patient drifts on to the deadlier shallow beyond. The history of many families, certainly my own on all sides, is arterial rupture (which in no case has been fatal, and that only in advanced life), followed in time by sudden cessation of the heart in diastole from softening of its fibres; and this last morbid change has always given distinct evidence of its approach and not come like a thief in the night.

Such, then, is my view of the natural history of the fatty heart: it is the last development of a long pathological process, the longest and most striking with which we are yet familiar

Of course it is not asserted that fatty degeneration of the heart never has any other antecedents; but this is its history as ordinarily encountered in practice. Occlusion of the coronary arteries, or rather partial occlusion, is the cause of the decay of the heart-wall. In one case death may take place suddenly, unexpectedly. In another, and far more commonly, when the wall is weakened dilatation commences, or rather recommences, and as hypertrophy's arresting hand is lifted so the symptoms of a failing heart are developed, and all the skill and pains in the world can never strengthen that failing heart, or even do much to stave off the inevitable end. When a patient with an hypertrophied heart and hard arteries begins to find the bulk of urine falling, and then heart symptoms showing themselves, with or without any coexistent valvular disease, the transient eye can read the beginning of the end. And this end is far, far more common than sudden death in the midst of apparent health, where the heart has undergone little or no preceding enlargement.

Fatty degeneration of the heart is common with ill-fed drunkards. But it has nothing to do with obesity, and is as comnon in lean persons as with stout persons. It has no relation to the growth of adipose tissue. It is a decay of the muscular fibrillæ, which undergo in life the same molecular changes as are found in the production of adipocere after death. Fat takes the place of muscular tissue within the scarcolemma, and the heart stops contracting because it is the seat of mural decay, in other words is "rotten."

A species of acute fatty degeneration of the heart goes on whenever a high temperature is maintained for some time, as in the specific fevers. Indeed, in relapsing fever, where the temperature runs very high, the heart becomes so weakened that death from syncope is not rare in the stage of convalescence.

The rebuilding of the cardiac fibrillæ after a sharp pyrexia is sometimes very slow, and months may elapse before the patient is equal to much exertion. The most pronounced cases, in my experience, of cardiac adynamia due to acute fatty degeneration have been those of young adults who have had typhoid fever, several of them medical men.

Then there is fatty infiltration, a growth of true adipose tissue outside the heart and to some extent within its structure. Here fat is deposited betwixt the fibrillæ, which are pressed upon by these fat-cells. A certain amount of adynamia in the heart is the result. Such fatty growth is usually found in obese persons of lax fibre. It is by comparison with fatty degeneration a somewhat uninteresting pathological condition.

Then there is a condition of adynamia in the heart, and also in the diaphragm, which, in its features, simulates fatty degeneration in conditions where the assimilation of albuminoids is impaired. It is commonly seen where the liver is disturbed, and instead of elaborating the proteids brought to it by the portal vein (or perhaps peptones not converted once more into proteids) into the serum-albumin of the liquor sanguinis, the liver turns them into lithates and bile acids, in consequence of which the heart and diaphragm are ill-nourished. Being ill-nourished they are deprived of much of their energy, with the result that the pulse is feeble, the heart-sounds weak,

there is cerebral anæmia, there is breathlessness in effort (partly from feebleness in the diaphragm), and the general condition which is associated with fatty degeneration is closely simulated. Indeed it is the "double" of fatty degeneration. To this state I have given the name of "Heart Starvation," for which a critic in the London *Medical Record* accused me of "the attempt to dress up well-known clinical facts in strange and startling phraseology;" continuing: "Apart from the language in which they are disguised, there is not a fact mentioned in this essay which is not also a commonplace to every experienced practitioner" (August, 1881). Despite this harebrained frivol of self-satisfied ignorance, many men of sound judgment regard the essay as a useful contribution to medicine on a subject on which little is known. If this occurs in a comparatively young person it would hardly be likely to be mistaken for a truly senile change. But when it occurs in a person who is of that age when senile changes may be looked for, it is not always possible to distinguish betwixt it and fatty degeneration of the heart, as in the case given above as occurring in my early days. It is really this condition of malnutrition grafted upon an old-standing valvular lesion which brings the patient to the doctor very often. Fortunately it is a remediable condition, which fatty degeneration (as described above) certainly is not.

The condition of the heart-muscle is a matter on which more general information is desirable. It is not flattering to our profession to hear patients say that years before they had been told they had fatty degeneration of the heart and must soon die suddenly, and yet then were well. The condition which had been diagnosed as "fatty degeneration" was really that of its double, "heart starvation."

A CONTRIBUTION TO THE STUDY OF CORYZA VASOMOTORIA PERIODICA, OR SO-CALLED "HAY FEVER."[1]

By JOHN N. MACKENZIE, M.D.,

SURGEON TO THE BALTIMORE EYE, EAR, AND THROAT CHARITY HOSPITAL, BALTIMORE, MD.

"Nunquam ita quisquam bene subducta ratione ad vitam fuit,
Quin res, ætas, usus semper aliquid opportet novi,
Aliquid moneat, ut illa quæ te scire credas, nescias,
Et, quæ tibi putaris prima, in experiundo ut repudies."
—TERENCE, in "Adelphis," Act V.

WHEN the phenomena of a given disease or unnatural condition are inexplicable by known pathological laws, or do not come within the range of that speculation which empirical fact and scientific experiment allow, it is customary to seek in the term "idiosyncrasy" a convenient refuge for acknowledged ignorance. This applies with especial force to the affection in question, the peculiar features of whose clinical history have been submitted to this lazy explanation. The well-recognized, but imperfectly understood personal susceptibility to certain forms of local irritation, which is the sad prerogative of the sufferers from this disease, has always been the stumbling-block in its investigation and the rock upon which the various speculations as to its nature have been wrecked.

Hasty generalizations based on the study of conditions external to the organism, to the exclusion of pathological agencies within, together with deductions drawn from isolated cases, and the uncertain testimony of the laity, have given rise to a variety of names indicative of its supposed etiology, such as "hay fever" or "asthma," "pollen fever" or "poisoning," "rose" or "peach cold," etc., appellations which should be discarded and forgotten, as they not only tend to perpetuate erroneous views and to introduce elements of confusion into the investigation, but also, by a diversion of the mind from mere essential conditions, have in no small measure contributed to retard progress in the therapeutic management of the disease.

While the term *coryza vasomotoria periodica*, suggested in the title of this communication, does not meet all the requirements of a logical definition, it may nevertheless be used provisionally until more exact knowledge of the affection furnishes data for the construction of a better. For, as will be shown below, the disease is essentially a coryza, showing, in most cases, a decided tendency to periodic recurrence, and dependent upon some functional derangement of the nerve-centres as its predisposing cause.

Until within the past few years clinical and experimental inquiry has been directed to the investigation of the most prominent exciting external influences provocative of the attack, and other and more important agencies have been entirely overlooked, or set aside as the general or special expressions of an idiosyncrasy, an explanation which is practically meaningless and conveys no definite or intelligent idea concerning the essential nature of the disease. While it is undoubtedly true that the inhalation of certain forms of matter, and pollen is only one of them, exercises an unquestionable irritative influence in the production of the paroxysm, it is, at the same time, equally certain that in a large proportion, if not all, careful inquiry will discover this influence to be purely secondary or accidental—to be dependent upon some local or constitutional condition. Although a number of investigators had previously labored with praiseworthy zeal to establish a definite pathology of the disease, the first to open the way to the rational solution of the problem was the late Dr. George M. Beard, of New York, who, by carefully selected statistics, pointed out the importance of the neurotic element as a factor in its production.[1] According to Beard, hay fever is a neurosis, a functional disease of the nervous system, an affection of modern life and of the nineteenth century. While he does not explain exactly in what such a neurosis consists, while his researches are open to fair criticism, and while his conclusions cannot be unreservedly accepted, they served, at least, the important purpose of lifting medical thought from the grooves to which it had been confined by the supporters of the pollen and bacteria speculations, and diverting it into newer and more fruitful channels.

Beard, and those who preceded him, not only deprecated the possible etiological importance of catarrhal affections of the upper air-passages, but went so far as to say that the very opposite state of affairs existed, and that the subjects of "hay fever," so called, were exempt from nasal and other forms of catarrh. The first, perhaps, to correct this erroneous impression and to point out the important rôle which disease of the naso-pharyngeal, cavities plays in the production of hay fever was Dr. Daley of Pittsburg, who, in 1881,[2] showed that, in a proportion at least of cases, there is local disease of the nose or naso-pharynx, without which the exciting cause is innocuous; and futhermore proved by clinical evidence that the cure of the affection may be effected through the removal of the local intrinsic condition.

The following year, Dr. Roe, of Rochester, published the favorable results of his treatment of the disease by operative procedures directed to the hypertrophied membrane in the nasal chambers.[3] According to Roe, hay fever is caused by the contact of the pollen of grasses or flowers and other irritating particles in the atmosphere with the nasal mucous membrane, which in certain individuals is rendered peculiarly susceptibie by virtue of disease, either active or latent, of the naso-pharynx, associated with hypertrophic catarrh of the nasal passages.

In the course of some experiments made by me on the healthy and diseased mucous membrane, with refer-

[2] *Vide* Archives of Laryngology, April 1, 1882. Dr. Edson had previously (letter to New York MEDICAL RECORD, 1878, vol. ii., p. 317) called attention to the fact that all cases of the disease presented one or more of certain symptoms referable to the nose, as great sensitiveness of the nasal membrane, coryza, persistent sternutation, naso-pharyngeal catarrh, etc.

[3] N. Y. Medical Journal, May 12, 19, 1883.

ence to nasal cough and the determination of an area in the nostril for the production of the various reflex phenomena associated with nasal disease,[1] the following facts were ascertained, whose application to the disease in question will, I venture to think, throw some additional light upon its pathology: 1. That in the nose there exists a well-defined sensitive area, whose stimulation through a local pathological process, or through *ab extra* irritation, is capable of producing an excitation which finds its expression in a reflex act or in a series of reflected phenomena. 2. That this sensitive area corresponds, in all probability, with that portion of the nasal mucous membrane covering the turbinated corpora cavernosa. 3. That nasal cough is produced only by stimulation of this area, and is only exceptionally evoked upon irritation of other portions of the mucous membrane. 4. That all parts of this area are not equally capable of generating the reflex, the most sensitive spots being probably represented by that portion of the membrane covering the posterior end of the inferior turbinated body and the septum immediately opposite. 5. That the tendency to evolution of reflex phenomena varies in different individuals, and is probably dependent upon the varying degree of excitability of the erectile tissue. In some the slightest touch is sufficient to excite the reflex act, while in others chronic hyperæmia or hypertrophy of the cavernous bodies seems to evoke it by constant irritation of the reflex centres, as occurs in similar conditions of other erectile organs, as, for example, the clitoris.

Apart from experimental proof of such localization—viz., to the posterior and inferior portion of the nostril—I showed, from my clinical observation, (1) that in cases where reflex cough is present, these are the portions chiefly, if not solely, involved; (2) that the act may be produced here at will by artificial stimulation of the diseased area, and (3) dissipated by local applications to, or removal of the same; (4) that foreign bodies only excite cough when they are imparted in the sensitive area; and (5) that polypi give rise to reflex phenomena only when they arise from or impinge upon the sensitive portions of the area; and lastly, a point of importance as bearing on the treatment, (6) that where *complete* atrophy of the turbinated structures exists, as, for example, in certain cases of ozœna, reflex cough is not present, nor can it be induced by artificial stimulation.

These facts are not alone true of cough and asthma; my experience furnishes me with a series of cases where they could be demonstrated as true of various other reflex phenomena originating in diseased conditions of this area, and I have already called attention to the reflexes[2] which I have met with (cough, pain in the ear and larynx, redness of drum membrane, etc.) in the course of operative procedures in this region.[3]

Since I first directed attention to the posterior end of the inferior turbinated body and septum as the most sensitive spots to reflex-producing impressions, I have received several communications confirmatory of the views expressed in my paper, which have also derived support from the publications of other writers. Thus, the observation that reflex asthma arises from nasal disease only when the posterior portions of the sensitive area are in some way involved, either directly from a pathological condition of the parts or from the irritation of a polypus,[4] has been confirmed by Dr. Roe,[5] who explains the more frequent occurrence of the paroxysms at night by the gravitation of blood to the sensitive area. The same author, moreover, in his recent paper on "hay fever,"[1] points out the fact that, in the majority of cases, the seat of irritation during the attack is the inferior turbinated bone and posterior portion of the septum, thus furnishing additional confirmatory clinical evidence in favor of localization of the reflex area in the lower and posterior portions of the nostril.[2] While these observations go to show that the most sensitive spots are represented by the area indicated above, it is but fair to state that a different opinion is entertained by a German confrère, well known from his labors in this special field. In August, 1883, there appeared in Germany an interesting brochure from the pen of Dr. Haek, of Freiburg,[3] in which this writer maintains, as the result of independent experiment, that the anterior extremity of the inferior turbinated bone is the point from which all reflexes take their origin, and that those arising from stimulation of other portions of the nostril only occur, secondarily, through congestion of the cavernous tissue of this circumscribed locality.

Like Daly and Roe, Haek holds that morbid conditions of the nasal membrane play the most important part in the etiology of the disease. He also believes that there are two factors in the production of the paroxysm, viz., a hyperæsthetic condition of the terminal filaments of the fifth and olfactory nerves, and an increased irritability of the cavernous tissue, caused, as a rule, by local nasal disease, and inclines to the belief (also held by Roe) that the neurasthenic symptoms are secondary to the nasal affection, calling attention, at the same time, to the fact that the latter may coexist with a general neurosis without having any connection with it.[4]

Finally, Dr. Harrison Allen advances the view[5] that "hay fever" depends solely upon obstruction of the nostrils (from deflection of the septum, hypertrophy of soft parts and bone, turgescence of nasal mucous membrane), and that the cure consists simply in removing the obstruction (or tendency thereto) in the nasal chambers. According to his experience, sufferers from hay fever and allied disorders have one feature in common—the inferior turbinated bones lie well above the floor of the nostril, an anatomical peculiarity which subjects their bulging mucous membrane to additional irritation from extraneous substances.[6]

It would appear, then, that the truth is irresistibly emerging into recognition that certain abnormal conditions of the nasal passages are necessary to the production of the *ensemble* of phenomena which form the classical picture of so-called hay asthma. Although the results arrived at by different observers, working independently of each other, and starting out in some instances from different standpoints, are not altogether harmonious, they present nevertheless a singular unanimity in their convergence to a common point—in their recognition of the importance of remedial measures addressed to the nasal chambers as a prime factor in the therapeutic management of the disease. While, then, it is probably true that certain states of the nasal passages are necessary to the production of a paroxysm, it is, at the same time, equally demonstrable that these are not always dependent upon well-defined local nasal disease, but that, in a number of cases, such conditions are originally brought about by abnormal excitability of the vasomotor centres from inherited or acquired disease. The problem, then, presents for consideration two important con-

[1] On Nasal Cough, and the Existence of a Sensitive Reflex Area in the Nose, American Journal of Medical Sciences, July, 1883. The results of these experiments were first brought before the Baltimore Medical Association in the early part of 1883, and subsequently before the Medico-Chirurgical Faculty of Maryland (April, 1883, *vide* Transactions), and the American Laryngological Association (May, 1883, *vide* Transactions).

[6] Allen reports several cases successfully treated by removing the obstruction to respiration. Cases have also been treated with the cautery by Dr. Sajous of Philadelphia (reported at last meeting of the American Laryngological Association), whose conclusions on the subject do not differ from those of Dr. Roe.

ditions; on the one hand the local nasal phenomena, and on the other the etiological relations of the central nervous system. In allotting to each its respective causative significance, care should be taken, in avoiding the Scylla of the neurologist, not to be too closely attracted to the Charybdis of another form of specialism.

Approaching the question from this standpoint, and guided by my personal experience, I believe that our definite knowledge of the etiology of the disease may be briefly expressed as follows:

1. The essential, distinguishing feature of the paroxysm of so-called "hay asthma" resides in an exalted condition (erethism) of the nasal erectile tissue, and especially that portion occupying the posterior end of the inferior turbinated bone and the septum immediately opposite. This latter area corresponds to the distribution of the spheno-palatine branches of the superior maxillary nerve, as distinguished from the nasal branch of the ophthalmic, which latter supplies the more anterior portions of the nasal fossæ. The former nerves, derived through the ganglion of Meckel, probably therefore contain the vaso-motor nerves which govern the erection of the turbinated tissue, and hence the localization of the sensitive area becomes the key to the mechanism of the paroxysm and brings us nearer the solution of the pathological process that sets it in motion.

So far as my observation goes, every attack is attended with more or less swelling of the erectile tissue, which is more pronounced in the lower and posterior parts of the nostril. This swelling, occasionally inconsiderable, is often sufficient to produce absolute and complete closure of the nasal fossæ. I have moreover, so far, never seen, nor have I been able to find the record of a single case where paroxysms of hay fever occurred where the tissue was completely atrophied or destroyed by disease. In two cases under my observation, the nasal chambers were markedly capacious, but, at the same time, the erectile tissue was well developed. Finally, the cure of the affection by the artificial destruction of the erectile bodies amounts to a demonstration.

2. This exaggerated irritability of the cavernous tissue may be directly due to the constant presence of congestion or other pathological conditions of that structure, the result of direct or indirect (reflex) irritation from *ab extra* influences, *plus* a hypersensitive condition of the vasomotor centres begotten of their prolonged excitation by the irritating influence in the nostril; or it may be brought about, in the first instance, by an exalted state of the central nervous system, leading eventually to disordered functional activity of the vasomotor nerve-centres; or, finally, a hypersensitive condition of the latter may be conditioned by other pathological states of the system as a whole, or as the result of reflected irritation from its individual parts.

I am inclined, therefore, to transfer the point of greatest excitability from the peripheral ends of the nerve filaments to the nerve-centres themselves. While I do not deny the possibility of a hyperæsthetic condition, or even organic changes in the terminal filaments of the sensitive nerves, as an occasional factor, and while fully aware of the want of experimental proof in favor of the view advanced, still it seems to me a more adequate, a more comprehensive explanation of the varied phases of the disease. Upon this theory can be best explained, moreover, the occurrence of paroxysms from irritation reflected from various parts of the body remote from the nasal passages. The weight of clinical evidence, too, is in favor of disordered functional activity of the nerve-centres, as against organic alteration of the peripheral sensitive nerves. Finally, it is probably not at the terminal ends of these filaments, but in the centres themselves, that the perception is awakened which differentiates one form of irritant from another; that the nerves themselves are but the passive channels through which the impression is transmitted, and that the production of a paroxysm by a given irritant will depend, other things being equal, upon the, so to speak, discriminating power or peculiar susceptibility of the centres themselves.

3. There is practically an infinitude of causes, external and internal, which may precipitate the nasal orgasm, such as various forms of matter suspended in the atmosphere (pollen, different forms of animal life, etc.), or the erection of the tissue may be conditioned by those influences that are commonly productive of erection of the nasal corpora cavernosa, such as varying meteorological relations, various forms of reflected irritation, or, finally, it may be occasioned through psychical causes. It follows, therefore, as a corollary to the above, that any one irritant is insufficient of itself to provoke the attack, the latter being only possible either from disordered functional activity of the nerve-centres, or local structural disease.

4. The power of a given local irritant to produce such impression, and the violence of the resulting attack, in all probability depends upon its physical properties and the length of its sojourn in the nasal cavities. Thus, the peculiar glutinous nature of some substances, as for example pollen, the irregular surfaces of others, as the golden-rod [1] and similar substances, will give rise to more prolonged irritation than substances of smooth contour, which are readily swept out of the nostrils.

5. Apart from its accidental occurrence with the flowering of certain plants, etc., the marked periodicity of the paroxysm in some cases, its regular appearance at a certain hour and on a certain day, so far from overthrowing its neurotic nature, points to some functional derangement as its possible cause. This tendency to periodical return of a given state is characteristic of certain morbid states of the nervous system, of which the so-called functional aphonia is a prominent example. It is not, therefore, stepping beyond the bounds of legitimate speculation to suggest this as the explanation of a certain number of cases.

6. Whatever be the original cause of such special tendency to erection and consequent evolution of reflex phenomena, the essential part of the mechanism of the paroxysm is the orgasm of the erectile area. This is the main-spring of the machinery by which it is set in motion, and without which the onset of the attack is impossible.

From what has been said above, it naturally follows that the rational treatment will consist (1) in diminishing the reflex excitability of the turbinated tissue; or, failing in that, (2) the partial, or, if necessary, complete destruction of the tissue itself.

The first indication must be met (1) by tonic remedies addressed to the nervous system, and by the exhibition of such drugs and methods as experience has shown control reflex excitability (the bromides, belladonna, chloral, counter-irritation to nape of the neck, etc.); (2) by the careful search for, and intelligent treatment of any pathological condition which may be regarded as a source of reflected irritation; and (3) by simple topical treatment of any existing nasal disease or irritation. In carrying out the second indication care should be taken to sacrifice as little of the erectile tissue as possible. It would accordingly be better to commence by removing or destroying that portion which covers the posterior end of the inferior turbinated bone, and, if necessary, that covering the septum immediately opposite; or, in other words, *that area which contains the greatest number of filaments of the sphenopalatine nerve.* Should this not accomplish the desired result, any additional sensitive spots should be located by means of the probe, as has been done by Roe, and appropriate treatment adopted.

The destructive agent used in any given case will vary according to circumstances. It may be said, in general,

[1] The golden-rod has also been regarded as the cause of hay fever. See editorial article on the Pathology of Hay Fever, by Dr. Frank Woodbury, in the Phila. Med. Times, December 1, 1883, p. 175

that hypertrophic enlargements of the turbinated bodies are best removed, if practicable, with the cold wire snare; swelling of the cavernous tissue over the septum is best treated with the galvano-cautery, while for complete destruction of erectile tissue, the latter agent or electrolysis is the best agent we possess.

Reference has been made several times above to reflected irritation of a distant organ as a factor in the production of the paroxysm. In order to illustrate this point, and at the same time make good the assertion of the fact, I will insert the following case:

Mrs. ——, aged thirty-seven years, married twenty years, the mother of one child, now eighteen years of age, came in the early part of April of this year to consult me on account of severe "hay fever." She has resided all her lifetime in a small manufacturing town on the banks of one of our Maryland rivers, and in proximity to a malarial district. Family history unimportant. Several of the neighbors suffer from paroxysms similar to her own. She is herself a woman of average intelligence, of spare habit, dark hair and eyes, good disposition, not inclined to be hysterical, nor easily frightened; is "dyspeptic," and suffers greatly from inability to digest her food. Without possessing a decidedly nervous temperament, in the common acceptation of the term, a more or less pronounced neurotic tendency expresses itself in a certain unnatural acuteness of the senses, and susceptibility to psychical impressions. Has never suffered from any nervous disease, with the exception of occasional neuralgic pains in the course of the fifth nerve, which have, however, of late, ceased to give her much trouble or concern. Has had malarial fever, and for the past four years has suffered from constant ovarian trouble. The left ovary is probably the only one involved, the condition being some chronic inflammatory disease. Has suffered for two years from "hay fever." Prior to her ovarian trouble, enjoyed excellent health and exhibited no tendency to catarrhal disease of the nose or throat.

The paroxysms are ushered in, as a rule, by chilly sensations, followed by violent and uncontrollable sneezing, intense redness of the conjunctivæ, increased lachrymation and spasm of the lids. During the attack she cannot see to read or write, any attempt to use the eyes being accompanied by great pain, photophobia, etc. The voice soon becomes husky and nasal, considerable mucus is expectorated from the throat, and a profuse watery and slightly mucous secretion is discharged in abundance from the nostrils. There is generally superadded to these symptoms a short barking cough, which often continues for several days after the subsidence of the attack. During the latter, the nostrils are always completely closed, so that nasal respiration is impossible. Pain is felt across the bridge of the nose and in the frontal and occipital regions, pain in the ears and tinnitus are nearly always experienced, and the meatuses feel as if stopped up by a foreign body. The amount of asthma accompanying the attack varies greatly, being at times more pronounced than at others. During the paroxysm pain is always felt in the left ovary, and any existing pain of that organ aggravated. The ovarian pain comes on after sneezing, and occasionally continues after the paroxysm has subsided. The attacks come on at all seasons of the year, and bear no definite relation to the conditon of the atmosphere as regards moisture or dryness; but are worse in spring and fall, *i.e.*, in the seasons of greatest temperature changes. They come on at all hours of the day, and she is often awakened from her sleep by the sudden accession of a paroxysm. The slightest exposure to draughts of any kind suffice to bring on the attack; the accidental unfastening of her night-dress at the neck during sleep, stepping from the bed to the floor, going about in her stocking feet, or changing her shoes for her slippers, and other equally trivial causes have frequently precipitated it. It is also brought on by physical or mental over-exertion, or by emotional excitement.[1] The attacks are not modified by diet, dust has little or no effect, while gas and smoke of various kinds produce a disagreeable, smothering sensation with some dyspnœa, but are insufficient to provoke the characteristic phenomena of the paroxysm. There are some plants that cause slight sneezing; but although frequently exposed to a pollen-laden atmosphere, exposure has never produced a paroxysm. The attacks invariably appear and are more severe at the menstrual period, appearing sometimes at its commencement, sometimes at its close. This latter condition of affairs has lasted for one year. They last generally for two days and one night, after which all the discomfort she suffers from them passes gradually away. She averages about two attacks a week, during which she is confined to her room, and often to bed. They sometimes leave her in a state of nervous prostration, from which she slowly recovers.

By the protection of the nasal passages from the contact of air during the attack, the paroxysms are somewhat mitigated in severity, except at the monthly period, when this has no effect. Residence at the sea-shore invariably gives relief; except during menstruation, when the attack is as severe as when at home.

During the intervals between the attacks, she does not suffer from nasal or throat trouble, beyond the accumulation of a slight amount of mucus in the nasal passages upon arising in the morning, with occasional dryness of the throat and huskiness of the voice. These phenomena are, moreover, of quite recent development.

Physical examination.—Nothing to indicate visceral disease, apart from the morbid condition of the ovary. No disease of auditory apparatus, larynx, trachea, or lungs. Anterior nasal passages apparently perfectly healthy. The posterior extremities of the inferior turbinated bodies, as seen in the rhinoscopic mirror, without being notably enlarged, present an ashy gray color often seen in hypertrophy of these bodies. The nasal fossæ are perfectly free and symmetrical. The lower border of the inferior turbinated bones cannot be seen in the mirror, and are not elevated above the nasal floor in front. There is no malformation or irregularity in the skeleton of the nose or other part of the face. The mucous membrane of the nasal pharynx is congested, and covered here and there with a faint film of transparent secretion. The mouths of the Eustachian tubes are normal in appearance. The lower pharynx is congested and studded here and there with small granules (commencing granular pharyngitis). No irregularity in the conformation of the pharyngeal cavities.

The treatment adopted in this case was in accordance with the indications laid down above, with special attention to the diminution of excitability of the erectile area. The nasal passages were kept thoroughly cleansed and protected against local irritation. Anodyne and alterative applications and acetic acid were made to the congested surfaces with the understanding that, should they fail to relieve, the galvano-cautery was to be resorted to.

At the end of one week little improvement was noticed; but at the close of the second marked change for the better had occurred, both as regards the number and severity of the paroxysms. At the expiration of six weeks the attacks had lost their distinguishing characters, the only annoyance from which the patient suffered being an occasional brief access of sneezing. At the two menstrual periods which intervened during this time, however, she had attacks resembling the original paroxysm, but greatly modified in severity. At the present writing, the sneezing has so markedly diminished, that it no longer gives her much concern, and her last monthly period was passed without the slightest nasal discomfort, although she was convinced that it was inevitable, and had pre-

[1] The patient attributes a great deal of her trouble to the excitement and mental anxiety which she underwent while in constant care of the wounded in her husband's factory, where accidents to the hands were constantly occurring.

pared herself for the attack. What the final result of this case will be I am, of course, unable to say, but from the present outlook, operative procedures will doubtless be unnecessary.

Remarks.—The above case shows, among other things, that the paroxysms of the disease commonly called "hay fever," may be brought on in the same individual by a variety of agencies differing entirely in origin, character, and mode of operation. At times they are produced by causes which are ordinarily provocative of common coryza, at others from the increased irritative stimulus given to a morbid process in a distant organ, or finally, they are occasioned by impressions of a purely psychical nature.

The attacks at the menstrual epoch are readily explicable by the physiological erection of the nasal corpora cavernosa which occurs at that period; for, as I have pointed out elsewhere,[1] in a certain proportion of women these bodies become enlarged and engorged during menstruation, the swelling of the membrane subsiding with the cessation of the catamenial flow. This turgescence may be bilateral, or confined to one side, may be inconsiderable and give rise to no inconvenience, or, on the other hand, the swollen bodies may include the nostrils and give rise to various reflex phenomena. In the "hay fever" sufferer, anything that tends to produce swelling of this tissue excites at the same time the tendency to the production of the reflex phenomena characteristic of the disease. In this particular case the chief, and, under certain circumstances, the sole excitant of the paroxysm was the utero-ovarian excitant of the menstrual epoch.

The history would point to a hypersensitive condition of the vasomotor nerve-centres, the result, perhaps, of constant irritation reflected from the diseased ovary, as the chief predisposing cause, or so-called "idiosyncratic" influence in this particular case. It is fair, too, to look upon the increased excitability of the erectile bodies, and the consequent repeated attacks of cough, as responsible for the amount of existing nasal disease.

The practical outcome of the above conception of the disease is simply this: Those who recognize in it the foundation of a rational therapeutic, and direct their treatment accordingly, will relieve all, and cure a large proportion of their patients; while those who blindly accept the traditional fallacies of the theory of external causes must continue to divert themselves with perpetual palliative experiment, and cling to the gloomy belief of the Englishman, that the only cure for the disease is patience, if removal from the British Isles is impossible, thanking God, at the same time, that there are only thirty days in June![2]

Apocynum Cannabinum.—Canada or American Indian hemp bark has a very persistent bitter taste, contains tannin and gallic acid. Is sometimes emetic, and causes diaphoresis; also cathartic, like jalap. It promotes expectoration, also drowsiness, increases the urinary secretion and diminishes the force and fervency of the pulse, like aconite or digitalis. It is most used in dropsy, and as a tonic and alterative in dyspepsia. Dose of powdered root, five grains, as an anti-periodic, twenty grains as an emetic. Decoction of ℥ j. to Ojss. of water, and boiled down to a pint; a wineglassful three times a day, as a diuretic, or ʒ j. of the bark of the root in ℥ viij. of water, ℥ ss. every six or eight hours. This is one of those remedies which should always be thought of in obstinate cases of cardiac or hepatic dropsy. Its diuretic action is frequently prompt and even extraordinary. It is the basis of Hunt's remedy for renal diseases. Although apocynum is used by some as gin and bitters, yet it is very disagreeable to others, and some persons far advanced in dropsy will almost rather die than swallow the simple infusion. A large addition of chimaphila or wintergreen will aid its diuretic powers and improve its taste.

WARBURG'S TINCTURE.

Hints for Simplifying and Cheapening It.

By JOHN C. PETERS, M.D.,

NEW YORK.

Some time ago I was so impressed with the shrewd hints of The Record about Warburg's tincture that I have made a careful study of that complex preparation, which I hope will be instructive to its readers.

In the tincture 42 ounces of various ingredients are to be dissolved in 500 parts of proof spirit, which is about half alcohol and half water, by placing them in a water-bath for twelve hours, then expressing them and adding 10 ounces of disulphate of quinine, the whole mixture being replaced in the water-bath until all the quinine is dissolved.

The process seems simple, but it may safely be assumed that a great residuum of resinous, bitter, and aromatic substances will be left behind.

Next to quinine the most important ingredient is aloes, of which 1 lb. British, or 16 ounces avordupois, or 7,000 grains are to be dissolved in the 500 ounces of proof spirit. There are next 4 ounces, or 1,750 grains of rhubarb. Third, 4 ounces, or 1,750 grains of angelica seeds, which is a simple aromatic tonic, spice, or stimulant, like aniseed, calamus, and the like. Fourth, 4 ounces, or 1,750 grains of the so-called *confectio damocratis*, which is a mild confection of opium, which once contained sixty-two ingredients, with about 5 grains to the ounce of opium. Nearly a century ago the London physicians substituted the *confectio Londonense*, made of opium, 6 drachms; long pepper, 1 ounce; ginger, 2 ounces; caraway seeds, 3 ounces; syrup, 1 pint. There is 1 grain of opium in every 36 grains, and the dose is 10 to 30 grains. Hooper says: "To the credit of modern pharmacy this is almost the only confection of opium that now remains of all those complicated and confused preparations called Damocratis, Mithridate, Theraic, etc. It more nearly approximates the virtues of all of them than any other, and may be considered an effectual substitute for them in practice. It is a very warm and stimulating confection and admirably calculated to soothe pain and restlessness, and sustain strength in low fevers." Fifth, 2 ounces, or 875 grains of *elecampane*, or less than 2 grains to the ounce: all its virtue a redue to a slightly peculiar camphor, which gives it its odor. Sixth, 2 ounces of saffron. Seventh, 2 ounces of fennel seeds. Eighth, 1 ounce, or less than 1 grain to the ounce, of gentian. Ninth, 1 ounce of zedoary, which is almost identical with ginger. Tenth, 1 ounce of cubebs. Eleventh, 1 ounce of myrrh. Twelfth, 1 ounce of camphor. Thirteenth, 1 ounce of boletus laricis, which is a purgative comparable to jalap and senna.

To sum up, in each ounce of Warburg's tincture we have about ten grains of quinine; fourteen of aloes; four of rhubarb; one of opium; two of elecampane; two of saffron; one of gentian; one of ginger; two of fennel seeds; one of cubebs; one of myrrh; one of camphor; and one of boletus or jalap or senna.

In building up his tincture Warburg probably took a hint from the German and French so-called Paracelsian elixir of life, which is composed of aloes, nine parts; gentian, rhubarb, zedoary, saffron, and boletus laricis, or larch, or purging agaric, each one part; digested in proof spirit two hundred parts, and of which the tonic and alterative dose is one or two drachms.

The European tincture of rhubarb is made with cardamom and coriander seeds, and saffron. The angelica seeds, fennel seeds, elecampane, saffron, zedoary, cubebs, and the little myrrh and camphor are pleasant aromatic additions to the tincture; and the one grain of gentian, and one grain of boletus or jalap do not deserve a great deal of attention.

The question arises whether a few aloes and rhubarb pills with quinine and spices will not accomplish almost all that Warburg's tincture will.

Or if a liquid preparation is preferred any physician can build a formula for himself with simple tincture of aloes and liquorice, U. S. P.; tincture of rhubarb and cardamoms, U. S. P.; or tinct. rhei et sennæ, U. S. P., made with rhubarb, senna, coriander and fennel seeds aided by a little paregoric and compound tincture of gentian—the latter made with gentian, bitter orange peel and coriander seeds—which will complete the whole, unless one prefers to add a few drops of tincture of myrrh and fluid extract of cubebs.

DELIRIUM CLOSELY RESEMBLING MANIA À POTU, FOLLOWING THE FREE USE OF MORPHINE.

By S. W. DANA, M.D.,

NEW YORK.

The patient, a youth of seventeen, of good constitution and temperate habits, during an attack of acute peritonitis lasting seven days took morphine from two to nearly six grains daily—about twenty-eight grains in all. During the first four days his mind remained clear and active, though the morphine given was sufficient to reduce his respirations to twelve per minute. There were brief periods of sleep, not amounting to more than three or four hours in twenty-four. During the last three days there was much less sleep and occasional light delirium. After the morphine was discontinued the delirium gradually assumed most of the characteristic features of *delirium tremens* and continued three days. During this time insomnia was absolute. The patient had delusions of hearing and sight; heard imaginary persons calling out to him; described their appearance and repeated their words; often fixed his eyes upon and clutched at imaginary objects in the air; was in constant movement and made frequent attempts to get out of bed; had important matters to attend to, and felt injured in being restrained. The pupils of his eyes were rather wildly dilated.

Meanwhile the general condition of the patient was otherwise good. His pulse and temperature were normal. He took a half pint of milk every three hours, and had a perfectly natural action of the bowels every day. Abdominal tension and tympanitis were rapidly disappearing, and convalescence from the peritonitis was progressing favorably. Under these circumstances I refrained from medication, confidently expecting that natural sleep would soon supervene. When, however, the delirium had continued three days with no indication of abatement, I prescribed, with the view of procuring sleep, the following potion:

℞. Potass. bromid.	℥ ss.	
Chloral hydrat.	grs. xv.	
Morph. sulphat.	gr. ⅓	
Aqua	q. s.	M.

Twenty minutes after taking this dose the patient fell into a quiet sleep, which continued sixteen hours, save momentary interruptions every three hours, when nourishment was given. At the end of his sixteen-hour nap the patient awoke cheerful and sane. His subsequent convalescence was rapid, and there was no further delirium.

Two symptoms *usually* met with in *delirium tremens* were not present in this case, namely, anorexia and muscular tremor.

Tetanus following Heaton's Method for the Cure of Hernia.—The editor of the *Peoria Medical Monthly* states that two patients who were recently operated upon by the Heatonian method died a few days afterward from tetanus. A third patient suffered severely from an extensive phlegmonous inflammation of the whole lower limb.

THE INHALATION OF SULPHURIC ETHER, WITH A DESCRIPTION OF AN AUTOMATIC-SUPPLYING INHALER.

By FRANZ HEUEL, Jr., M.D.,

SURGEON TO THE CITY HOSPITALS ON RANDALL'S ISLAND, PROSECTOR TO THE CHAIR OF SURGERY AND INSTRUCTOR IN OPERATIVE SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

The administration of anæsthetic vapors in graduated quantities and controllable by the operator has, for years, been a matter of investigation and study by the medical profession. Many forms of apparatus have been devised to accomplish this end, but the majority, while promising much in theory, fail, in practice, to answer all of the requirements which an instrument of this class should possess. Among the principal objections to these different forms of apparatus may be enumerated that of the unsatisfactory distribution of the anæsthetic fluid, giving rise to disagreeable and, sometimes, disastrous accidents; and the imperfect working of valves, obstructing free respiration and thereby rather asphyxiating than anæsthetizing the patient. Another objection is the difficulty which attends their thorough cleansing, a matter of some weight in these days of asepsis. Aside from which, if there is anything that will disgust a patient at the commencement of the administration of ether, it is an apparatus impregnated with the odor of vomited or expectorated matters. Finally, the intricacy of their construction often renders their management difficult, increases their expense, and, in a great many instances, adds to their bulk and difficulty of transportation.

For ordinary use nothing to date has been found better than the simple napkin or towel folded in the form of a cylinder or cone and having incorporated between its folds a piece of paper to give it the requisite amount of stiffness, thereby preventing the inhaler, when saturated with ether, from collapsing upon the face of the patient and excluding all air. Gross ignorance or criminal carelessness on the part of the administrator during inhalation may produce death by asphyxia, owing to the use of an ill-adjusted apparatus or the crowding upon the face of towels saturated with ether so that the patient is deprived of all air. Such accidents, however, must be exceedingly rare. As a fresh napkin or towel should always be used for each case, the cone will always be in a cleanly condition. This is more than can be said of a good many face-pieces where inhalers are employed. The too frequent removal from the face of the cone, for the purpose of replenishing the anæsthetic, may be avoided by placing a sponge, handkerchief, or piece of lint in the top of the cone to be saturated with ether. When additional ether is necessary it should be poured into the inverted cone as quickly as possible, since a few inhalations of pure air will neutralize, to a considerable extent, the anæsthetic effect already obtained. As has been aptly remarked by Dr. J. B. Roberts,[1] ether, in order to be properly administered, should be given in *large quantities* and with *little* air, while chloroform should be given in *small quantities* and with *much* air, otherwise the stage of excitement will not be overcome without considerable trouble and loss of valuable time; in fact, might lead the administrator to think the patient could not be fully etherized. A widely prevalent idea is that ether should be given with much air. In speaking of this as the "*Ether Folly*," Dr. J. B. Roberts says it "is almost universal. Often have I heard physicians say of a patient, 'He couldn't be etherized; I had to give him chloroform.' Now, the fault was not with the patient, but with the doctor. I doubt there being an individual or an animal in the world that cannot be anæsthetized with ether properly administered. . . . I do not advocate giving ether carelessly, but I assert that it is usually given inefficiently. More danger is to be found in this long-continued inefficient etherization than in the prompt method I describe."

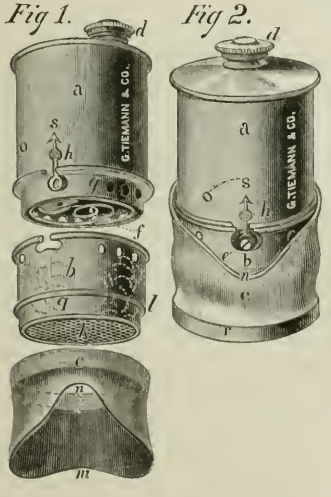
[1] Philadelphia Polyclinic, February 15, 1884.

The amount of vapor inhaled can be easily regulated by removing the cone a short distance from the patient's face and allowing him an admixture of atmospheric air when necessary, looking to its physiological effects rather than any arbitrary rules relative to an admixture with atmospheric air. Too great concentration of vapor need hardly be guarded against, as experience has taught us the comparative safety of inhalation of sulphuric ether.

A simple napkin or towel, therefore, will answer the purpose, and either is as safe as any inhaler can be, although both have their objections, chief among which is the large waste of ether consequent upon their use, especially in a warm room, as only a small quantity of the vapor given off can ever be inhaled; the larger part escapes by the side of the cone, enters the apartment, and interferes with the comfort of the surgeon and his assistants.

Hence, in constructing an apparatus for ether inhalation, the objects to be attained are, first, that it be more convenient, durable, and economical, though just as simple, easily managed, safe, and cleanly as the towel cone; second, that it present no possible difficulty to free respiration either by the inadequate diameter of its respiratory passages, or by inhaling or exhaling valves, which are apt to get out of order; third, that it be self-supplying, with the anæsthetic under perfect control, thereby avoiding the necessity of removing the instrument from the face to replenish with ether; fourth, that it present the air as nearly as possible saturated with ether, at the same time preventing its general diffusion outside of the body without impeding the patient's respiration; and, lastly, that it be inexpensive, and not bulky or cumbersome.

Fig 1. *Fig 2.*



To attain these desiderata I have devised an inhaler, constructed for me by Messrs. Tiemann & Co., of this city, which overcomes in a satisfactory manner all of the difficulties enumerated above. I have used it in hospital and private practice for the last nine months, and have found that it practically fulfils the theoretical requirements of a perfect inhaler.

It is constructed of thin nickel-plated brass, with a rubber face-piece, and is, when closed for transportation, a cylinder six inches long by three inches in diameter, being of convenient size to carry in the pocket, and consists, as shown in the accompanying woodcut, Fig. 1, of three parts, viz.: An ether reservoir, *a*; a respiratory chamber, *b*; and a face-piece, *c*, one placed below the other.

The ether reservoir is cylindrical in shape, holding about twelve fluid ounces. It has at the top, near the side, an opening, *d*, closed by a screw-cap and rubber washer for filling the reservoir. The screw-cap has drilled through its side, below the washer, a small opening, so that when unscrewed, before using the apparatus, by a few turns it will permit air to enter the ether reservoir to supply the vacuum left by the exit of ether through the stop-cock at the bottom.

At the bottom of the ether reservoir, near the side, is an opening closed by a metal stop-cock, *e*, continuous with which, and in a plane parallel to and one half-inch below the bottom, is a spiral coil, *f*, of small copper tubing, having perforations about one inch apart on the top or side nearest the reservoir. This pipe runs from the stop-cock on the side straight to the centre, and then spirally toward the periphery. To steady it, it is soldered at its outer margins to a ring, *g*, projecting from the bottom of the reservoir. The stop-cock has attached to it an index hand and chequered button, *h*, which moves on the outside of the reservoir, and indicates when parallel to the long axis of the reservoir that it is closed, *s*; when moved away from this axis toward *o*, that it is being opened. The ring *g*, projecting from the bottom of the reservoir, fits, by an accurate bayonet joint, into the top of the next cylinder, *b*, which is the respiratory chamber. Both the ring *g*, and the top of the respiratory chamber are pierced with corresponding holes five-sixteenths of an inch in diameter and about three-eighths of an inch apart. These I will designate as the respiratory openings. The bottom of the respiratory chamber is slightly turned in, forming a shoulder upon which is fitted a disk of wire gauze, *k*, to retain the evaporating medium and protect it from expectorated and vomited matter. Around the outside of the respiratory chamber, and one-half inch from the bottom, is soldered a piece of brass wire, *l*, to act as a shoulder to the top of the rubber face-piece, *c*, which fits over the bottom of the respiratory cylinder. Within the respiratory chamber and upon the wire gauze is packed washed sheep's wool, which I have found the best medium of evaporation for the ether, which drops upon it from the spiral coil above. Now it will be seen why the perforations in the copper coil are placed in the upper side, as the ether, when the inhaler is placed in the vertical position for use, must first fill the entire coil before it can escape from the openings, thereby ensuring an equal distribution of the anæsthetic fluid. For the same reason the coil is first run straight from the stop-cock to the centre of the ether reservoir, and then spirally to its periphery, as the inhaler, when in use, cannot always be kept in a strictly vertical position.

The face-piece, *c*, is made of soft vulcanized rubber, shaped like a truncated cone, with notches for the chin, *m*, and nose, *n*, to more accurately fit it to the face. Being made of soft rubber, it adapts itself equally well to a round, thin, large, or small face, a prominent or a flat nose. It will answer as well for a child as for an adult. In the former the chin must be placed within the face-piece, the rubber then covering the nostrils, mouth, and entire chin. In the latter a notch, *m*, in the rubber fits on the chin. At the top, and within the face-piece, a metal ring, *p*, is baked on, which firmly fits over the bottom, *q*, of the respiratory chamber.

In the use of the inhaler, as with any other appliance for the administration of anæsthetics, the following points should be observed:

The patient is first prepared by loosening the clothing about the neck and waist, so that there shall be no obstruction to respiration or circulation. The part to be operated upon is then made freely accessible. Should the patient have any artificial teeth they must be removed, in order to guard against their entering the respiratory passages or being swallowed. The assistant having charge of the etherization should place the patient supine upon the operating table or bed, with the head slightly raised upon a pillow, and should stand at the head o the bed. He should have within easy reach his inhaler

and a dressing forceps, with which to draw out the tongue should it fall back and cause closure of the glottis; or, if necessary, to remove pieces of egested matter. He should also be provided with a hypodermic syringe charged with brandy, whiskey, or diluted aqua ammonia, to use in case the pulse becomes feeble. A basin and towels will be necessary, in case the patient should vomit or expectorate. The assistant administering the ether should pay strict attention to the duties incumbent upon him, to the exclusion of even momentarily transferring his thoughts to the operation, or what may be going on in or about the room.

Everything being in readiness the inhaler, with the stop-cock still closed, is placed vertically over the patient's mouth and nose. It should be supported in this position by placing one hand on either side of the patient's face so that in case of necessity the movements of the head may be restrained. Occupying this position the administrator can easily determine the condition of the pulse from an examination of the carotid, facial, or temporal arteries. In a few encouraging words the patient is directed to "blow out" (exhale) forcibly, regularly, and to continue to do so as long as he can remember. The rubber fitting the face very closely the patient will necessarily be compelled to breathe through the sheep's wool and openings in the respiratory chamber, but neither of these impede in the least free and natural respiration. Hence the feeling of apprehension and sense of suffocation which usually disturbs him at this time when any of the ordinary inhalers are used is, to a large extent, avoided. I direct the patient to "blow out" because I have found this a much better plan with the average person than to request him to inspire deeply, as it is more easily comprehended and he will be obliged to take a deep inspiration as a necessary result of a long exhalation, thereby getting more of the anæsthetic and sooner coming under its effects.

After the patient has made a few respirations in this manner the stop-cock of the ether reservoir is turned on by the thumb of either hand supporting the inhaler on the face, permitting only a few drops of ether to flow in to the absorbent material in the respiratory chamber, so as to gradually accustom the larynx to it. In this manner, and at short intervals, more ether should be added until the full anæsthetic effect is obtained. Having reached this point it will be found that a much smaller quantity will answer to maintain its effect than usual. After being applied, the apparatus should not again be removed from the face, unless an urgent necessity demands it; otherwise the patient, by breathing pure air, would neutralize to a certain extent the effect of the ether already given, and thereby necessarily prolong its administration.

Care should be taken not to oversaturate the material in the respiratory chamber, lest the ether might flow over the patient's face. By the exercise of a little caution this can easily be avoided.

Sometimes, during semi-consciousness, when a patient forgets or refuses to exhale regularly, the respirations may be stimulated by asking him questions, asking him to count from one to fifty, or to say his ABC. Again, if the administrator will endeavor to guide the person's thoughts into agreeable channels, from the commencement of the etherization, by conversing with him on pleasant and familiar subjects, it will often have the effect of inducing pleasant dreams for the patient throughout the employment of the anæsthetic. By these means the patient often passes under the effects without a struggle or being in the least alarmed.

Should it become necessary, after anæsthesia is induced, to turn the patient on his side, the ether reservoir may be taken off and the respiratory chamber with attached face-piece only used, in which case small quantities of ether are dropped as needed from the supply opening, *d*, of the ether reservoir upon the absorbent material in the respiratory chamber. To prevent a too free diffusion of the vapor about the room the supporting hand may be placed over the respiratory chamber.

After using the inhaler, the face-piece should be removed and thoroughly cleaned by placing it in water; the sheep's wool, if desired, can be washed to free it from the products of respiration and then dried to be used again; but it is better to throw it away, as it is very cheap, and use new, fresh wool for each case.

The apparatus can now be put together for transportation, by reversing the face-piece (see Fig. 2) over the respiratory chamber and placing over the bottom the metal cap, *r*, which accompanies the apparatus.

From time to time it is well to put a drop of oil on the stop-cock of the reservoir, as the ether dissolves out the oil and makes the stop-cock turn with difficulty.

Progress of Medical Science.

Simulation of Unilateral Amaurosis.—To discover simulation of one-sided blindness, Dr. Bravais recommends the method of Snellen. This latter rests on the fact that if one writes with a red pencil on paper, the letters written cannot be recognized if seen through red glass. If one holds before the apparently healthy eye a red glass, and before the pretended blind eye any kind of glass, or none at all, and requests the simulator to read the red letters on the paper (which have not been before shown to him), and he can read them, the evidence of his simulating is clear; for if the second eye had really been blind, he would not have been able to recognize the red letters through the red glass.—*Medical and Surgical Reporter*, May 31, 1884.

Vinegar in Post-Partum Hemorrhage.—Dr. Grigg relates in the *British Medical Journal* the case of a "flooder" in whom a profuse hemorrhage was almost instantaneously arrested by the administration of vinegar. The uterus, which was flaccid and gradually dilating, contracted at once after the patient had been given a wineglassful of vinegar, and after the second dose of the acid the hemorrhage ceased entirely. He states that the pupil midwives are accustomed to give this remedy in preference to ergot, as its action is more rapid and certain. So rapid, indeed, he asserts, is its action, that he counsels against its use until after the expulsion of the placenta, for fear of causing a retention of that body.

The Treatment of Phthisis by Overfeeding.—Drs. Broca and Wins believe with Debove that anorexia is one of the chief causes of exhaustion in phthisis, and that a systematic overfeeding of consumptive patients by means of the stomach-tube exercises a most beneficial influence on the disease itself. Nitrogenous food is thebest, especially milk, eggs, and meat-powder. The quantity introduced into the stomach at a time must never exceed one litre. In most cases the food was well digested, the perspiration, cough, and dyspnœa diminished, and the patient increased in weight. In several cases the signs of excavation in the lungs became less distinct, though they never disappeared entirely.—*La France Médicale.*

Contraindications in the Use of Quinine.—Dr. Rabuteau has observed several cases in which nausea, vomiting, and pain in the stomach were caused by the administration of iodide of potassium and sulphate of quinine in combination. He cautions against the simultaneous administration of these drugs, and believes that the unpleasant symptoms were due to the setting free of pure iodide. He further asserts that quinine is contraindicated in women during menstruation. He cites instances in which women, who at other times showed no idiosyncrasy in this respect, were unable to take quinine while menstruating, because of the intense hypogastric pain which invariably followed.—*Allgemeine Medicinische Central-Zeitung*, May 17, 1884.

Hereditary Ataxia.—Dr. Lucas Championnière describes this affection, also called Friedreich's disease, which partakes of the characteristics of both multiple spinal sclerosis and progressive locomotor ataxia. It makes its appearance in childhood or in youth, thus differing from ataxia proper, which occurs during the second period of life. Like both the diseases which it resembles, Friedreich's disease usually occurs in individuals who are affected with some form of nervous disease, as hysteria, epilepsy, general paralysis, etc. Its peculiar feature is that it may attack several children in the same family. As yet it has been observed only a few times, Friedreich himself having seen but nine cases, in three families. An English writer has seen five children, in a family of nine, who suffered with it. Its course is regularly progressive to a fatal issue, again resembling ataxia proper. As to the lightning-pains, and habitual anæsthesia or hyperæsthesia in spots which occur in locomotor ataxia, these are wanting in hereditary ataxia; but there are present motor inco-ordination to an exaggerated degree, and impaired or abolished reflexes. Like multiple spinal sclerosis, this disease exhibits nystagmus, paralysis as to associated ocular movements, and disturbances of speech, while paralytic myosis and blindness are absent. There is also an absence of the bladder troubles, which are so frequently seen in locomotor ataxia, as well as of the gastric and laryngeal crises, and trophic disturbances. It will thus be seen that this disease resembles true ataxia in respect to the spinal symptoms, while it presents characteristics which prevent mistaking it for multiple spinal sclerosis. The anatomical lesion is located in the posterior columns and lateral fasciculi, which explains the clinical resemblance to both of the diseases with which hereditary ataxia has been compared.—*Archives of Pediatrics*, May 15, 1884.

Multiple Spinal Arthropathies.—Dr. J. Boyer reports in *Lyon Médical* of June 1, 1884, the case of an ataxic, forty-five years of age, in whom the trophic disturbances were an early symptom and occurred several years before inco-ordination of movement was marked. The joint troubles were manifested first by a spontaneous luxation of the hip, then the knees became swollen, and finally both feet became also swollen. The tumefaction of the feet was at first œdematous, and later became of a hard osseous consistency, most marked on the dorsal surface. The lesions in the feet were found after death to consist in an œdematous infiltration of the soft parts of the tarsal and metatarsal regions, marked hypertrophy of the head of the astragalus, of the os calcis, and of the scaphoid bone. At the tarso-metatarsal joint there was a complete union of the cuboid and three cuneiform with the metatarsal bones, with hypertrophy, softening, friability, and spongy degeneration of the anchylosed articular surfaces. Arthropathies of the feet in locomotor ataxia are of comparatively rare occurrence, yet, as has been shown by Boyer, Page, Charcot, and Féré, are not so infrequent as was formerly supposed.

The Diagnostic Value of Certain Symptoms in the Diseases of Children.—Professor S. M. Politzer formulates the following concerning the significance of individual symptoms in children's diseases (*Deutsche Medicinal-Zeitung*, May 19, 1884): 1. The symptom of a strongly-marked nasal tone in crying points to the probable existence of a retropharyngeal abscess. 2. A loud and very long-continued expiratory sound, with normal inspiration and the absence of dyspnœa, is significant of chorea major. Sometimes this sound resembles the bellowing of an animal, and may continue for a long time as the only symptom of chorea. 3. A thoracic, sighing inspiration indicates cardiac weakness. This is one of the first symptoms, appearing before cyanosis or pallor of the face, thready pulse, coldness of the extremities, or the other well-recognized signs of weak heart. 4. A marked diaphragmatic expiration, accompanied with a fine, high-pitched whistling, points to bronchial asthma. 5. A marked interval between the end of expiration and the beginning of inspiration renders the diagnosis of catarrhal laryngitis without exudation probable. 6. There is no special significance in the loud, sort of bleating, expiratory sound sometimes observed in infants during the first months of life. It seems to depend upon a modified innervation within physiological limits, and resembles the want of rhythm in the cardiac movements occasionally met with in the early years of childhood. The following symptoms are given by the author as of value in the early diagnosis of cerebral diseases: 1. A peculiar drowsiness, continuing for several days, unaccompanied by fever or other disturbance, is indicative of basilar meningitis. This is a more valuable sign than headache, vomiting, or a slow, irregular pulse, since the latter may occur in various extracranial diseases. 2. A tense, elevated anterior fontanelle points to intracranial effusion. If it be very prominent, resistant to pressure, and without a sign of pulsation, there is almost certainly an intermeningeal hemorrhage. A deeply-sunken fontanelle indicates inanition and a diminished volume of blood. 3. Very slow movements of the eyes, followed by fixity in one position, a vacant stare, and a peculiar lazy closing of the lids are signs of a beginning basilar meningitis. The character of the cry is of value sometimes in the diagnosis. 1. A fit of shrill crying, lasting for two or three minutes, accompanied by an expression of fear in the face, and coming on regularly an hour or an hour and a half after the child has gone to sleep, is the expression of night-terrors. Quinine, given in rather large dose one or two hours before bed-time, is an effectual remedy against this trouble. 2. Periodical crying-spells, of five or ten minutes' duration, coming on sometimes during the day but more frequently only at night, point to cramps in the bladder, provided that we can exclude intestinal or gastric colic. This is speedily cured by emulsion of lycopodium with or without belladonna. 3. Crying while at stool and an evident dread of the act of defecation are signs pointing to fissure of the anus. 4. Hard, continuous crying, expressive of severe pain, together with frequent putting of the hands to the head or rolling of the head in the pillow, are evidences of otitis media or pain in the ear from some other cause. 5. When for days and weeks the child cries on being moved, and when there is also profuse sweating and an elevated temperature, the disease is rickets. 6. Frequent crying, with habitual sleeplessness during the first two years of life, are found in anæmic and poorly-nourished children, or in those with congenital syphilis. Finally, Professor Politzer recounts some other single symptoms which aid in forming a speedy diagnosis. 1. The peculiar physiognomy of children suffering from congenital syphilis. The sinking in of the root of the nose, the sallow complexion, the scanty eyelashes, the yellowish edges of the eyelids, and the rhagades on the underlip are characteristic of hereditary syphilis. 2. A falling together of the alæ nasi, and an absence of all motion in them during inspiration, point to hypertrophy of the tonsils. 3. A weakness and loss of motion out of all proportion to the gravity or duration of the accompanying illness should raise a suspicion of infantile paralysis. 4. A partial loss of hearing after a sickness is often due to a circumscribed meningitis at the base of the fourth ventricle. 5. Depression of the mental faculties occurring after a severe infectious disease is frequently indicative of a beginning acquired idiocy. Strychnine exerts a favorable influence in these cases. 6. Retarded ossification of the skull may imply rachitis. 7. A stiff carriage of children in walking, standing, sitting down, or stooping, is observed in commencing Pott's disease. In children who do not walk there is a painful contraction of the features when they are lifted up or set down. 8. Constant vomiting of all ingesta, lasting for several weeks, in children with large heads but closed fontanelles, is a sign that an acute hydrocephalus is engrafted upon the chronic condition.

The Morbid Anatomy of Malarial Fever.—Vinogradoff, of St. Petersburg, has published an elaborate paper on this subject, based on his extensive experience in Bulgaria during the Russian-Turkish war, 1877–78. Some of the main results of his investigations are as follows: Like other infectious diseases, malarial fever manifests itself in a series of lesions of internal organs. The most generally spread lesions is parenchymatous inflammation, which affects chiefly the liver, spleen, heart, and kidneys, but occurs also, though less constantly and in a less considerable degree, in the lymphatic glands, nerve-centres, gastro-intestinal and sudoriferous glands, testes, and striated muscles. The parenchymatous changes consist mainly in opaque swelling of cellular elements, with their subsequent hyperplasia, or atrophy, or degeneration. In the liver the most frequent issue of a parenchymatous inflammation is local limited atrophy (though in some cases there occurs a diffuse hyperplasia of the parenchyma, as Kelsch and Kléner's observations show). The malarial parenchymatous inflammation of the kidneys, in a certain proportion of cases, shows a tendency to take a progressive development and to pass into an ordinary form of Bright's disease. The parenchymatous alterations in the heart consist in slight opacity and swelling, as well as in atrophy and brown pigmentation of muscle-cells. The parenchymatous changes in the spleen are almost exclusively limited to the lymphoid elements of the pulp. The malarial interstitial inflammatory process is spread less extensively than the former, and affects mainly the liver, spleen, and kidneys. The interstitial inflammation of the liver is characterized by the development of older fibrous tissue and young granulation-structure. The formation of the new interstitial tissue is not spread uniformly all over the organ, but is limited to certain regions, being localized mostly in the neighborhood of branches of the portal vein and between the lobules. In the spleen, the development of new interstitial tissue proceeds along the veins of the stroma; the capsule, also, being not unfrequently found thickened. In the kidneys the development of the interstitial tissue is observed both in the cortical and in the medullary substances, and, as in other organs, is of a diffuse character. The interstitial changes occur also in the deep muscular layers of the heart, in the testes, and in the lymphatic glands, especially in those situated within the abdominal cavity. The distribution of melanotic pigment over the organs is connected with lesions of blood-vessels. The vascular changes consist at first in swelling of the epithelioid lining of the capillaries, which may be so considerable as to lead to complete obliteration of the lumen of the vessel. Red blood-corpuscles become impacted between the enlarged epithelioid cells, and are gradually transformed into fine granules of yellowish and light-brown coloring matter. The latter is taken up by leucocytes and epithelioid tissue. The epithelioid cells undergo either proliferation, or fine granular disintegration, leaving then heaps of pigment-granules in the shape of scales, described by Frerichs and others. Fatty degeneration of the epithelioid lining of the capillaries of the brain is, according to the author, a most constant phenomenon in malaria, and is especially pronounced in the sites of extravasations. Pigment-masses are accumulated mainly in the spleen; and here again chiefly in the pulp, interstitial tissue, and vessels. The cells of the reticulum undergo partly proliferation with subsequent transformation into fibrous products, partly regressive modifications (albuminous and fatty degeneration). In the period of swelling many of these cells, as well as large lymphoid elements, absorb blood-corpuscles, which are slowly disintegrated and disappear, leaving light and dark-brownish pigment. In the bone-marrow, pigment is mostly found in the stellated cells of the reticulum. The pigment-masses accumulated in the liver are not formed on the spot, but arrive from the spleen through the vena portæ. Two main sources supplying pigment in melanæmia are the spleen and the bone-marrow. According to the author, this fact is proved by the occurrence in them of striking phenomena of disintegration of blood-corpuscles, by a considerable accumulation in them of coloring matter, and by their anatomical arrangements allowing pigment to easily enter into the circulation. Another source of pigment-formation is given in the migration, with subsequent disintegration, of red blood-corpuscles, observed in the brain. When disintegrating, some of the blood-corpuscles coalesce and form hyaline or diaphanous bodies or scales, identical with those found by Popoff in the brain of uræmic men and of uræmic and cholæmic dogs. Beside the liver, spleen, bone-marrow, and brain, the author observed deposition of coloring matter in the capillaries of the testes, gastro-intestinal mucous membrane, and papillary layer of the skin; in the lung it was seen in the interstitial tissue and epithelium of the alveoli; in the lymphatic glands it was present chiefly within leucocytes. As to the pigment itself found in malaria, it does not differ in any way from that derived from red blood-corpuscles in other diseases.—*London Medical Record*, June 16, 1884.

Jequirity in Persian Practice.—A Persian physician stated to Dr. Polak that jequirity was in frequent use by the oculists in his country in the treatment of pannus, corneal opacities, and pterygium. For the ensuing inflammation, usually lasting three days, they used local applications of milk, decoction of althæa, and mucilage of plantago psyllium (fleawort). If necessary, the treatment is repeated in fifteen or sixteen days, but never more than four times in succession.—*Centralblatt für Praktische Augenheilkunde*, May, 1884.

Resection of Muscles in Infantile Paralysis.—Mr. Keetley has recently undertaken the resection of part of the quadriceps extensor femoris in a case of infantile paralysis causing inability to extend the right knee. By shortening the weak, relaxed, and partly atrophied muscle, the operator hoped to increase its strength, with the aid of electricity during recovery from the operation. Mr. Willett has already resected the tendo-Achillis in paralytic talipes calcaneus, with good results, finding that the shortening of the abnormally elongated tendon enables the muscles of the calf to regain some portion of their lost functions, especially when the muscular wasting has been chiefly due to disease, and has not advanced too far. Mr. Keetley's patient was a boy aged six, who had suffered from paralysis of the right lower extremity for four years, and the muscular atrophy was not complete, yet sufficient to prevent thorough extension of the knee. A longitudinal incision was made in front of the thigh, about three inches in length, ending an inch above the patella; the skin was held apart by retractors, and one inch of the entire substance of the quadriceps was cut away with scissors, about two inches above the patella. The separated ends were united by means of about one dozen carbolized catgut-ligatures. Esmarch's bandage had been applied before operation, and only one small artery required ligature. The wound was dressed with a small iodoform-pad and carbolic gauze, and the limb placed on a back-splint at an angle of sixty degrees with the bed. The wound healed rapidly and perfectly, but as the operation was performed on May 5th, it is as yet too soon to determine the results as regards the function of the limb.—*British Medical Journal*, May 31, 1884.

Treatment of Furuncle.—The following treatment of furuncles is highly recommended in the *Revue Médicale* of June 7, 1884. The boil itself and the inflamed zone surrounding it are covered with a soft paste of honey and powdered arnica flowers, spread upon linen. The application is renewed every two hours until the pain and soreness have entirely disappeared, which they do by the second or third day at the latest. If the application is made in the initial stage, the boil is aborted within twenty-four hours.

False Pregnancy.—Dr. Delgado reports the following rather remarkable case of spurious pregnancy: A woman, aged thirty, married, separated accidentally from her husband for several months, presented herself in the hospital at Valladolid for advice, saying that she was pregnant and out of her reckoning. The greater part of the signs of pregnancy existed—suppression of the menses for about nine months, gradual enlargement of the abdomen to full-term size, increase of the breasts with pigmentation of the nipples, vomiting at the beginning and end of the pregnancy. She said she felt the movement of the child. On examination, ballottement, movements of the fœtus, and fœtal heart-sounds were absent. After four days in the hospital, labor-pains began, terminating by the expulsion of a great quantity of blood in dark clots and liquid by the vagina. At the same time there was violent hæmatemesis, which had to be controlled with ice and perchloride of iron. Three years later, when she had again been living with her husband for eleven months, the same series of phenomena occurred; the hæmatemesis, however, being less intense. On the most careful examination, no trace of mole, or of remains of placenta or fœtal membranes, could be discovered.

An Instance of Nervous Impressionability.—Dr. Blykaerts relates a curious case of a boy, thirteen years of age, who resembled Samson in that the cutting of his hair exerted an extraordinary influence upon him. At the first clip of the scissors he would begin to tremble, then he would suffer from ringing in the ears, vertigo, and dimness of vision. Then the pulse would become thready, and soon a state of complete syncope would come on. This would last for five or six minutes, and would then be succeeded by vomiting. The child was in apparent good health, but never had convulsions, and came from a family free from epilepsy. The treatment consisted in first accustoming the boy to handle the scissors himself and to snap the blades together. Then for a time one hair was cut each day, then a lock, and so on, until finally the peculiar impressionability was entirely overcome.—*Le Progrès Médical*, June 21, 1884.

Some Points Concerning the Physio-pathology of the Blood-vessels.—According to Ferraro (*London Medical Record*) the blood of diabetic patients under microscopic examination presents nothing characteristic to distinguish it from that of a healthy individual. The spontaneous coagulation takes place normally. In diabetics, the blood may coagulate in any point of the circulatory system, and give rise to the formation of thrombi causing more or less obstruction, wherever the conditions favorable to its spontaneous coagulation are found. The blood of rabbits surcharged artificially with glucose coagulates, but more slowly. When the intima of a large artery (the carotid) of a dog is destroyed either by mechanical or chemical means, or by a very high temperature, if the vasa vasorum be not injured at the same time, the blood circulating in the artery does not coagulate. On the other hand, there is thrombotic occlusion of the artery whenever the middle coat is injured as well as the intima, and especially if, besides the intima, the vasa vasorum have been destroyed. This experimental lesion of the intima of the carotid of the dog is similar to that which diabetes mellitus produces in man, in whom the intima of the arteries is often lost from desquamation of its cells, *endoarteritis diabetica desquamativa*. In both cases the circulating blood does not coagulate in the arteries despoiled of their intima, if the rest of the wall of the vessel be alive and nourished as in the normal state. Endarteritis diabetica, desquamative in form, described by the author in the organs of five diabetics, finds support in these experiments, the object of which was to produce in animals by other means a lesion of the intima of the arteries similar to that which diabetes produces in man. The results obtained agree in showing the influence of a vessel-wall thus altered on the blood circulating in the vessel. It is then possible that from certain morbid conditions the epithelioid lining of an artery or the whole intima may be lost, and yet for the blood traversing this vessel not to coagulate and not to form a thrombus, if other circumstances favoring thrombosis do not intervene. This being possible, since demonstrated by pathological observation in diabetes mellitus and by experiment, it must be held that the influence of the living arterial wall on its contained blood, by which its spontaneous coagulation is prevented, is not due exclusively to the epithelioid layer investing the internal surface, but also to the rest of the wall of the vessel. If the epithelial stratum be destroyed by any morbid condition whatsoever, the rest of the wall, if alive, may exercise the same influence on its contained blood. In the normal condition, the intima of the arteries receives the nutritive plasma partly from the blood circulating in the interior of the vessel, by which it is constantly bathed, and partly from that circulating in the vasa vasorum of the contiguous middle coat. If the vasa vasorum be destroyed, the neighboring intima is not always able to retain its vitality.

Cure of Hydrarthrosis by Electricity.—A patient was admitted to the service of Dr. Castano, of Buenos Ayres, suffering from hydrarthrosis of the knee. After a varied treatment by flying blisters, cauterization, compression, etc., had been tried without success, it was determined to employ the constant current from a battery of thirty-six elements. The result was most gratifying. By the fourth day the circumference of the articulation had been reduced some four-fifths of an inch; on the seventh day no fluctuation could be perceived, and on the ninth day the joint measured exactly the same as its fellow. Walking was difficult at first, but was much facilitated by the application of an elastic bandage.—*Revue Médicale*, June 7, 1884.

The Formation of Urea.—MM. Gréhant and Quinquand have been conducting some further investigations as to the places of formation of urea in the economy. They have estimated several times the amount of urea in the blood going to, and in that coming from, the spleen and liver. The blood from the hepatic, portal, and splenic veins always contained more urea than arterial blood taken from the carotid arteries. From this they conclude that the abdominal viscera form urea. It is also asserted that the proportion of urea is practically the same in arterial and venous blood from the limbs and head. Lymph and chyle collected from the thoracic duct after section of the medulla oblongata and the employment of artificial respiration have always been found to be richer in urea than venous or arterial blood.—*The Lancet*, June 14, 1884.

The Death-rate of Phthisis.—In a work recently published by Dr. Wurzburg on "The Influence of Age and Sex on the Mortality Due to Tubercular Phthisis," some of the generally accepted notions on this subject are overthrown. The opinion seems to have been commonly entertained that the greatest number of deaths from consumption occurred at about the twentieth year. But the statistics collected by Dr. Würzburg prove that, after a large percentage of infancy, the minimum death-rate is met with from three to fifteen years, and that then the rise is a gradual and steady one up to the period between sixty and seventy years. After that age a rapid decline is noted. These statistics are for Prussia, and embrace a period of five years from 1875 to 1879. The same condition has been noted in Sweden and the United States, with this difference, that in these countries there is no decline after the age of seventy years. In England, however, the highest death-rate falls between twenty and thirty years, and the lowest between fifty and seventy years. There is but a very slight difference in the percentage of deaths from tubercular phthisis between the city and the country.—*Medical and Surgical Reporter* June 14, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 19, 1884.

PERVERTED SEXUAL INSTINCT.

SIR THOMAS BROWN once wrote, platonically, that the act of procreation was "the foolishest act a wise man commits in all his life. Nor is there anything that will more deject his cooled imagination." The physician learns, however, that man, so far from tending toward this ideal, is more apt to show instincts of a violently opposite character, and finds, far down beneath the surface of ordinary social life, currents of human passion and action that would shock and sicken the mind not accustomed to think everything pertaining to living creatures worthy of study. Science has indeed discovered that, amid the lowest forms of bestiality and sensuousness exhibited by debased men, there are phenomena which are truly pathological and which deserve the considerate attention and help of the physician.

Some twenty years ago, a lawyer of Hanover wrote an article describing a form of sexual perversion to which he was himself subject, and defending the acts to which his morbid instincts prompted him.

In 1869 Westphal reported two similar cases, and described the condition as a congenital sexual perversion (conträre sexualempfindnng). Subsequently several other such histories were published, and in 1877, Krafft-Ebing, in reporting an additional case, gave a careful analysis of the condition, classifying it among the psycho-degenerative states. Drs. J. C. Shaw and G. N. Ferris, in the *Journal of Nervous and Mental Diseases* for April, 1883, presented a collection of previously reported histories, omitting, however, one which was published in THE MEDICAL RECORD. These gentlemen also related a case of their own. Up to that time only twenty-one cases were on record, three being reported by Americans, the rest mainly by Germans, and none at all by English observers.

In a recent number of the *Irrenfreund* (vol. xxvi., No. 1, 1884), Krafft-Ebing has reported six more cases. One of these was that of a merchant, now living in America, who wrote to Krafft-Ebing a letter which can but strike the attention. The patient says: "I have read your article in the *Zeitschrift für Psychiatrie.* Through it I am, in common with thousands of others, rehabilitated in the eyes of every thinking and generous man, and I offer you for it my warmest thanks. You very well know how those in our condition are despised and execrated. Though science at this late time has undertaken to investigate it, it still remains the object of detestation. I think that Ulrichs [the Hanoverian lawyer referred to] underestimates the number of its victims. In my native city (of 13,000 inhabitants) I knew personally twelve 'Urnings.' In a city of 60,000 inhabitants I know at least eighty." The writer then goes on to relate his own history.

The victims of this perverted instinct have been termed by Ulrichs and others "Urnings." If their number is as great as Krafft-Ebing's correspondent indicates, it is certainly a matter of importance. It is not improbable, however, that some of these are rather examples of vicious lust than of pathological perversions.

These so-called "Urnings" are persons whose sexual feelings can only be aroused by intimacy with their own sex; they have an irrepressible desire to act the part of the opposite sex. If men, as is generally the case, they try to dress, or walk like, and imitate the habits of women. The very act of dressing in women's clothes excites the sexual sense. They have a repugnance to normal sexual intercourse, and have no desire for it. They attach themselves to some other man, and form sometimes purely platonic friendships with him. More generally they find some fellow "Urning" with whom the sexual passion is easily excited by mutual masturbation or intercourse per anum. They sometimes form attachments for boys[1] or old men. They often masturbate while having lascivious images of the male beloved before their imagination.

In the reported cases of congenital perversion, the abnormal instinct begins oftenest as early as the eighth or ninth year, but shows itself at first, perhaps, only in an inclination to adopt the manners and practices of girls or women. The victims show the somatic basis of their trouble in various ways. There is often an hereditary psychopathic or neuropathic taint. Epilepsy is sometimes present. There are noticed in some cases, though not often, defects of the genital organs, such as hypospadias or epispadias, small or defective testicles. The hair on the face is sometimes thin, the voice almost always soft. The "Urnings" have a mincing gait, and sometimes the hips are broad like those of women. Exacerbations of the perverted feeling appear periodically. It may be accompanied with melancholia and end in insanity or suicide.

The mental peculiarities of these unfortunates have much in common. They are of the artistic, poetical, and imaginative temperament, often exhibiting a tendency to rather weak philosophizing. Sometimes they are of a vigorous understanding. In most cases there is great mental distress felt through a consciousness of their unnatural instincts. Two or three have, like Ulrichs, boldly defended their practices.

Medical jurists have devised a number of technical terms to cover the practices that follow from these sexual aberrations, which, it should be borne in mind, are still classed in all cases as crimes. The intercourse between woman and woman (Lesbian love) is known as tribadism. That between man and man, or unnatural intercourse between man and woman, is known as sodomy. When the victim is a boy it is known as pæderasty.

If congenital perverted sexual instinct is a pathologi-

[1] "Thou shalt not corrupt boys," is one of the commandments in the Teachings of the Twelve Apostles.

cal rather than a vicious condition, the query arises whether there is any remedy for it. The history of cases reported shows that sometimes the instinct is cultivated and intensified by bad surroundings in childhood, such as, for example, the exclusive society of women and immoral nurses. Excessive sexual indulgence seems to increase it, and we may question whether in a few cases the condition would have ever developed, were it not for an early abuse and misdirection of the sexual powers. In conditions of nervous exhaustion and weakness, the symptoms are exaggerated, and Krafft-Ebing, in his last communication, reports the case of a married man, previously healthy, who experienced an entire change in the sexual feeling, which lasted for twenty-five years. He was then cured by general faradization and other tonic measures.

In conclusion, we believe it to be demonstrated that conditions once considered criminal are really pathological, and come within the province of the physician. We have undertaken, therefore, the disagreeable task of laying some of the facts regarding sexual perversion before our readers. The profession can be trusted to sift the degrading and vicious from what is truly morbid.

We cannot do better than append the conclusions which Krafft-Ebing has reached upon this subject. He says: "1. There exists a congenital absence of sexual feeling toward the opposite sex, at times even disgust of sexual intercourse. 2. This defect occurs in a physically differentiated sexual type and with a normal development of the sexual organs. 3. Absence of the psychical qualities corresponding to the anatomical sexual type, but the feelings, thoughts, and actions of a perverted sexual instinct. 4. Abnormally early appearance of sexual desire. 5. Painful consciousness of the perverted sexual desire. 6. Sexual desire toward the same sex. 7. The sexual desire remains purely platonic or finds gratification in mutual onanism, or in feeling of the object of the affections. Often there is self-pollution, but for the want of something better. 8. There are symptoms of a morbid excitability of the sexual desires, together with an irritable weakness of the nervous symptoms, so that sensuous feelings, magnetic sensations, and even pollutions occur in simply touching the object of the affections. 9. The perverse sexual impulse is abnormally intense and rules all thought and sensation. The love of such individuals is excessive even to adoration, and is often followed by sorrow, melancholy, and jealousy. 10. People afflicted with this abnormity frequently possess an instinctive power to recognize one another."

In this last conclusion we cannot agree. The power of mutual recognition is not instinctive but acquired.

GERMAN MEDICAL JOURNALS.

The German-speaking race is abundantly supplied with medical journals of every conceivable kind, and they reflect very well the character of the German medical mind. The number of special journals is particularly great. There are quarterlies, and monthlies, and even weeklies devoted to gynecology, neurology, psychiatry, ophthalmology, etc.

The leading journals are the large weeklies: the *Berliner Klinische Wochenschrift*, the *Deutsche Medicinische Wochenschrift*, the *Wiener Medizinische Wochenschrift*, etc. These are not framed upon the English or American plan. They rarely contain any formal editorials, and but very brief notes of current events. They are filled with heavy original articles, most of which are so laboriously scientific and minutely technical that they would appear to the American mind extremely dull. Interspersed with these, however, there are not rarely the rich original contributions to medical science which makes Germany so famous. A characteristic of German periodical literature is that it is almost all written by the Professors or their assistants, or by some of the various instructors at the universities. One hears almost nothing from the general practitioner who is so prominent a person in American journalism. There has of late, to be sure, been something of a revolt started. Dr. Julius Grosser, a practising physician at Prenzlau, has dared to start a weekly journal in the interest of his confrères, and despite the frowns of the great men of the universities. His journal, the *Deutsche Medizinal-Zeitung* gives a practical summary of progress in all departments of medicine, and must prove extremely useful. A few other journals of a somewhat similar character exist, one, the *Central-Zeitung*, being published, like some of the French journals, three times a week. A further evidence of the effort which is of late being made by German journalists to supply the practical needs of the physician is the growth of therapeutical literature. There has recently been established an excellent journal devoted to therapeutics alone, and a popular and often-quoted monthly journal, called *Memorabilien*, edited by Dr. Betz, devotes itself chiefly to therapeutics. The *Zeitschrift für Therapie* is almost everything but therapeutical.

The various *Archives*, in which are contained the results of laborious researches in physiology, pathology, pharmacology, and clinical medicine, embody a mass of literature to which there is no parallel in other countries.

A very large part of German periodical literature consists of minute, carefully recorded observations, pathological, physiological, and clinical. These cover not only things which are practical but also everything having a bearing on medicine. This habit of careful observation and detailed statement makes an article very tedious; but it is the method which ensures progress in a science like that of medicine. In order to furnish the essentials of all these elaborately recorded studies, and to allow a person with moderate leisure to follow the progress in the various departments, journals devoted simply to abstracting and condensing are published, and have now become quite numerous. There are the various monthly and yearly *Jahrbücher* and *Jahresberichte*, besides three or four weeklies, which are entirely devoted to this kind of work. Indeed, the summaries of medical progress are nowhere done with so much painstaking conscientiousness as by our German confrères. They err only in sometimes analyzing with too much care articles which are worthless. In this kind of work, the Germans can teach the profession of other nationalities. In the technical part of journalism, or journalism proper, they are far behind England and America. The jour-

nals do not voice the opinions of the profession at large; they have no strong writers, and when the weekly notes are lengthened out into the dignity of editorial it is generally to express some comment on local and personal matters.

A CRITICISM UPON THE VALUE OF SULPHATE OF CINCHONIDIA (CINCHONIDINE).

It is known that the sulphate of cinchonidia is very much used as a cheap substitute, and probably as an adulterant, of quinine. A recent contribution to the pharmacology and therapeutics of this drug, by Professor J. Marty, of Rennes (*Bulletin Général de Thérapeutique*, May 30, 1884), is, therefore, of much interest. Having given it to healthy persons, and in various types of malarial fever, he comes to the conclusion that cinchonidia has two serious defects: 1. Its extreme variability of action in healthy and sick men. 2. The ease with which it may provoke toxic manifestations in doses necessary to produce its therapeutic results.

Professor Marty thinks that it should be given in doses double those of quinine, and that it is then an efficient agent in the benign types of malarial fever. For the pernicious types it should not be trusted. It does not act well in the various forms of malarial headache and neuralgia.

We believe that Professor Marty's conclusions will be found to harmonize in the main with the practical experience of those who have used it in this country. Cinchonidia is a very useful substitute for quinine in the milder affections in which that drug is indicated, but it is liable to disappoint the physician in some cases.

RECTAL ANÆSTHESIA.

M. A. Poncet publishes in the *Lyons Médicale* an interesting contribution to the subject of rectal anæsthesia. It appears that M. Roux, in 1847, first thought of and suggested the plan of giving ether by the rectum (*Compt. rendu de l'Academie des Sciences*, February 1, 1847, p. 146). He did not, however, try it himself. Three months later Dr. Vincente-y-Hedo published the results of his experiments in injecting liquid ether into the rectum of rabbits (*Gazette médicale de Paris*, 1847, p. 317). Naturally, these experiments led to no practical results. A little later M. Marc Dupuy injected ether and water into the rectum of animals and produced insensibility, but with so much injury to the mucous membrane that the experiments were not repeated on man. In the same year, 1847, Pirogoff, of St. Petersburg, first produced anæsthesia in man by the introduction of ethereal vapor into the rectum (*Recherches pratiques et physiologigues sur l'etherization*, Saint-Petersbourg, 1847). He employed the new procedure in a number of cases, recognized its advantages, and urged its adoption. Different apparatuses were constructed, and the use of ethereal vapor per anum was adopted by Simonin at Nancy, for a year or two subsequently.

After this, it seems that the subject was dropped entirely for over thirty years. According to M. Poncet, there is no record of the employment of rectal anæsthesia until M. Mollière reported his cases last spring. Since that time, aside from ten trials made in this country, rectal anæsthesia has been made the subject of a communication to the Société de Biologie by M. Bebierre (*Journal de Médecine de Paris*, April 19, 1884). M. Delore has published an article upon the same subject (*Gazette des Hôpitaux*, March 20, 1884), and M. Dubois has recommended the use of chloroform vapor per rectum instead of ether.

M. Poncet now comes forward with the record of five cases in which he has himself employed rectal anæsthesia with ether vapor; and he sounds a note of warning against this new procedure. In four of his cases, success was tolerably good, but in the fifth, that of a woman thirty-seven years of age, severe collapse took place after insensibility had been produced, and it was with the greatest difficulty that the patient was restored.

M. Poncet is most decidedly of the opinion that the administration of ether per rectum is a dangerous procedure, and one not to be adopted by careful surgeons. This is the view which is now held in New York.

PROFESSIONAL "PIDGEN" ENGLISH.

No; not quite that bad perhaps, but some of the lucubrations of our writers are more remarkable for ambiguity than for scientific value, and certainly far richer in bad grammar than in sound pathology or therapeutics. We are aware that not every practitioner has had the advantage of a collegiate education; some apparently never graced the benches of an "old-field" school. But there is a notable proportion of college-bred men in the profession, men who have an A.M. or an LL.D. after their names, but who write vile English, both as regards the wrong use of words and the wrong use—or non-use—of grammar.

A very generally abused word in medical literature is, perhaps, "apt." The persistency with which writers use this word for "likely" and "liable" is really marvellous. The following are a few examples of the wrong use of words, found within a few minutes during a cursory glance at current journals: medical doses for medicinal doses, dilation for dilatation, ligated for ligatured, diagnosed for diagnosticated, teaspoonsful for teaspoonfuls, official for officinal, analogous for similar, and entroitus for introitus.

There is very common misuse of "where" for "in which." Some—almost every—writer speaks of a "case where," *e.g.*, "cases are on record where post-mortem of persons," meaning "in which the post mortem examination," for *post-mortem* should never be unaccompanied by the *examination*. A writer in a current journal says: "We have two classes to treat—young women and married women," leaving the reader to infer that all young women are single and all married women are old. Another has manufactured a new word—diuretico-mucilaginous. We have an idea that he is the same who says: "He began to pass large quantities of dissolved stone," though he was not the author of the following: "Dr. ——, of ——, wants treatment for cross-eyes that came suddenly on a girl. This is paralysis of the rectimuscles of the eyeball, internal or external accordingly as the squint is con or divergent." It has long been known that woman rules the household, but a correspondent of a St. Louis *Comic Medical Journal* says: "Menstruation is evidently the chief governor of woman and her

family relations." This is important information, and should be strictly kept from the ears of "woman's rights" women. Another writer in the same journal has with a stroke of the pen cured every adult dyspeptic in the country: "Dyspepsia is par excellence a disease of infancy." We wish it were true. But there is a dangerous man somewhere whose friends especially should know about him. He says: "I have found the following to be very beneficial in the treatment of gonorrhœa, which I would like to give to any one who wants it, hoping it will be of some benefit to the medical fraternity." He should mend both his morals and his grammar. But seriously, the bad English of the profession is deplorable.

THE PROPOSED S. D. GROSS PROFESSORSHIP OF PATHOLOGICAL ANATOMY.

We have received a circular asking us to assist in the effort to secure, "in some medical school," the endowment of a memorial professorship to be designated the S. D. Gross Professorship of Pathological Anatomy.

We will cordially support any movement looking toward the commemoration of the remarkable work and noble character of the late Professor Gross. We but voice the sentiments of many, however, when we ask if some fitter memorial for the general profession to contribute to could not be found than that of a professorship in a private medical college. This chair naturally should be in Jefferson Medical College, though it is not so specified. And many, perhaps most, physicians would prefer to contribute simply to the memory of Gross, not at the same time to the resources of a prosperous medical institution.

A LESSON TO BE REMEMBERED.

On the morning of Friday, September 1, 1854, the cholera suddenly attacked a number of persons residing in the sub-district of Berwick, in the city of London. The outbreak was confined to the immediate vicinity of a well situated on Broad Street.

This well was the centre of an infected district: "a person starting from thence and walking at a moderate pace would have got beyond its limits in three minutes" (English Rivers Pollution Reports). During the month of August preceding the outbreak, only twenty-six cases of cholera were reported to the London authorities from this district (Berwick).

The epidemic reached its height on September 2d, and declined about fifty per cent. on the 5th; after which it dwindled off until the 20th, this day being the first on which no death took place. The total number of deaths in the district from the 1st up to this date was 609.

Investigation showed that about seventy-eight hours before the great outburst of the disease a child was attacked with cholera in the house No. 40 Broad Street, and its dejections were emptied into a drain which ran within a few feet of the well. The water from this well was very popular with the neighborhood.

Analysis showed that it contained in 100,000 parts 137 parts total solids and 7.72 parts organic and volatile matter. It was clearly shown that nearly all the persons attacked with the disease had drank the water from this well.

In one case, an old lady and her niece, residing at a distance, had been in the habit of having the water sent to them daily. They both had cholera, while none of their neighbors contracted it.

The history of this well should be engraved on the mind of every sanitarian. The activity displayed by health authorities in searching out and stopping the water from city wells shows that it has not been lost on them. The use of such water for the preparation of aërated drinks is the more dangerous, since such beverages are prescribed for invalids.

The history of the cholera in Manchester and Glasgow illustrates most forcibly the importance of a pure water supply for cities. Until 1851 the people of Manchester and Salford obtained water partly from wells and partly from the River Irwell. Both these sources were much polluted with excrementitious matters.

In 1851 a pure supply of water was introduced into these towns. The following figures, taken from the report of the Rivers Pollution Commission, show the mortality during the polluted and pure-water periods:

Total mortality in Manchester and Salford, polluted-water period: 1832, 890; 1849, 1,115; pure-water period: 1854, 50; 1866, 88.

The history of the disease in Glasgow affords evidence equally conclusive. Until 1859 the water supply was drawn from the Clyde, and was polluted by the drainage of towns higher up the river. After that year a pure supply was obtained from Loch Katrine.

Total mortality in Glasgow, polluted-water period: 1832, 2,842; 1849, 3,772; 1854, 3,886; pure-water period: 1866, 68. Mortality per 10,000 of population, polluted-water period: 1832, 140; 1849, 106; 1854, 119; pure-water period: 1866, 16.

These facts are not new to sanitarians who have studied the subject, and they can be multiplied to any extent desirable to prove the intimate connection of cholera with water supply. We repeat, then, we are glad to see that the health authorities in this city are so thoroughly alive to the necessity of inspection of wells, and are so strenuously in favor of preventing the use of the water from them for drinking purposes.

Cholera and the Price of Disinfectants.—The alarm over cholera has caused a marked increase in the demand for disinfectants and cholera drugs. A member of a large drug firm in this city states that opium has advanced twenty-five cents per pound in the past few days. It may be questioned whether the rise in opium comes from the scare or the shortness of the crop this year. Sulphate of morphine is twenty cents per ounce higher and oil of peppermint has recently advanced. The demand for camphor is increasing, and a rise is expected. Chloride of lime is being largely purchased, and is twenty-five cents per hundred pounds higher. Carbolic acid crystals have advanced from twenty-five to thirty per cent. There is considerable buying by France in England also.

The Chicago Medical Journal appears in a new and much improved dress, and announces as its editors Drs. James Nevins Hyde, W. W. Jaggard, and Harold N. Moyer.

News of the Week.

Death from the Bite of a Rattlesnake.—A snake-charmer in this city, named James Reilly, was bitten in the hand by a rattlesnake, and died in forty-eight hours in consequence. Large amounts of whiskey and ammonia were given, but without avail. An autopsy on the body was made by Dr. W. H. Welch.

The Summer Corps of Sanitary Inspectors went to 4,504 houses last week, and visited 24,099 families, finding 811 sick persons, to whom they gave prescriptions or medicine, and tickets for excursions. Of the patients, 365, nearly all of whom were children, suffered from diarrhœa, 118 had trouble with the respiratory organs, and 70 were sick of diseases.

Lepers to be Put on Exhibition.—A unique variety of the moral show has been devised by a Californian, calling himself Dr. C. C. O'Donnell. He has secured two Chinese lepers with a large portfolio of photographs of other cases, and he proposes to travel East and exhibit them. The show is in the interest of anti-Chinese immigration. Dr. O'Donnell claims that there are between two hundred and two hundred and fifty lepers in San Francisco already, and that the disease is increasing.

Faith-Surgery.—The following is an interesting specimen of advertisement that appeared recently in a daily paper: "Faith Surgery.—My dislocated shoulder and broken collar-bone instantly set and cured by Rev. Dr. ——, Christian Healer [address is here given]. Was able to do heavy family washing next day. Mrs. ——. Doctors and ministers can interview me."

The Congress of German Naturalists and Physicians will be held at Magdeburg, September 18 to 23, 1884. The medical and surgical work at this meeting promises to be very considerable. Sections are organized for all the specialties, and many prominent physicians have already furnished the titles to the papers.

Prizes for Surgical Essays.—The Medico-Surgical Society, of Bologna, has offered two prizes of 500 lires each. First prize, Sgarze, for the best essay on The Surgical Treatment of Pulmonary Cavities. Second prize, Gajani, The Surgery of Diseases of the Stomach. The essays must be written in Italian, French, or Latin.

The Progress of Cholera in Europe.—The epidemic of cholera continues to increase, as will be seen by the accompanying figures of deaths: July 9th, Toulon, 11; Marseilles, 23. July 10th, Toulon, 11; Marseilles, 59. July 11th, Toulon, 13; Marseilles, 74. July 12th, Toulon, 22; Marseilles, 65. July 13th, Toulon, 35; Marseilles, 57. July 14th, Toulon, 11; Marseilles, 66. July 15th, Toulon, 20; Marseilles, 69. Cases of cholera are said to have occurred in the surrounding country. Two cases have been reported also in Transylvania and one at Nimes, France. The reported occurrence of cases in Paris and Lyons is denied. Dr. Koch continues to assert that the disease will spread throughout Europe, but thinks that it may be kept from America this year at least. The Paris Académie de Médecine has been asked to give an official opinion regarding the cholera, its mode of prevention, etc. This the Académie seems disinclined to do because the Government refused to take its advice as to holding the fête of July 14th. If the Académie treats cholera in the same discursive manner that it did typhoid fever, it will be a year before its opinions will be formulated. Nearly all countries have quarantined against the French Mediterranean ports. Our own Government will oblige vessels from Europe bound for the United States to have certified clean bills of health from the American consuls.

The Number of Cases of Small-pox in London last week was 1,200. Some parts of the city are reported to be in a very filthy condition.

Disinfecting Toulon.—"Every means of disinfection at Toulon," says *The British Medical Journal*, "has been adopted. The city is watered with a solution of carbolic acid and chloride of lime. Those who have died from cholera are buried at a great depth underground. Railway travellers are sprinkled with carbolic acid solution. The soldiery are encamped outside the town. The sick sailors are put on board the Entreprenaule to be examined; the cholera-patients are removed to the St. Maudrier Hospital, which is reserved for them. The crews have been placed on vessels at anchor outside the port. The Ministers of War and the Marine have given orders to the authorities of arsenals to deliver to the civil authorities all the material for camping out that they may require. MM. Brouardel and Proust arrived on Tuesday, June 24th, at Toulon, with a Ministerial decree to effect whatever measures they judge necessary for the public safety; to ordain the evacuation of entire districts, and of the city itself, if requisite. Dr. Rochaud left Paris for Toulon on Tuesday evening, also MM. Strauss and Rout, in order to continue their scientific researches. They are also commissioned to make a strict inquiry into the origin of the outbreak."

Fifty-second Annual Meeting of the British Medical Association.—This association will hold its annual meeting at Belfast, on July 29 to August 1, 1884. President, Dr. A. T. H. Waters, of Liverpool. President-Elect, Dr. James Cuming, of Belfast. The address in Medicine will be delivered by Dr. William M. Ord, of London; that in Physiology by Dr. Peter Redfern, of Belfast; that in Obstetrics by Dr. George H. Kidd, of Dublin. A number of special discussions have been arranged. Among them we note one on Albuminuria, introduced by Dr. George Johnson; one on the Plaster Jacket, introduced by Dr. L. H. Sayre; one on Extra-Uterine Fœtation, introduced by Lawson Tait; one on a New Antipyretic, introduced by Dr. Alexander Collie and by Dr. Dujardin-Beaumetz. There will be the usual annual museum, and a large number of excursions and entertainments have been planned.

Precautions Against Cholera.—The members of the summer corps of visiting physicians and the Fruit Inspectors, recently appointed by the Health Department, have received supplementary instructions in regard to their duties from Dr. E. H. Janes, the Assistant Sanitary Superintendent, in view of the possible advent of cholera in this city and its vicinity. All cases of contagious disease discovered, whether the patients are

under treatment or not, are to be immediately reported to the health bureau, giving name, age, and residence of the patient. In view of the possible advent of cholera, special attention is to be paid to shanty neighborhoods in unsewered portions of the city, where excretæ are deposited in shallow vaults or upon the surface of the ground, and where the water supply is from springs or surface wells.

The Minnesota State Medical Society.—The physicians of Minnesota need stirring up, as well as those of Louisiana, according to the *Northwestern Lancet*. The last State meeting was a success socially, but in scientific and practical work and in attendance it was a failure.

The Hospital Saturday and Sunday Funds in England amount to about a million and a quarter of dollars annually.

Death from the Administration of Bichloride of Methylene.—Another death must be scored against the comparatively little used anæsthetic, bichloride of methylene. In this case the victim was the daughter of a physician of Lancashire, England. The young lady, twenty-three years of age, was to be submitted to a slight surgical operation. The anæsthetic had been given only three minutes, and scarcely ten minims had been inhaled, when the heart suddenly ceased to beat. Respiration also stopped. All efforts at resuscitation proved unavailing. A previous examination had failed to show any signs of heart or lung disease.

The True Use of a Porous Plaster, according to a Milwaukee druggist, is "to retain the back in its proper place and let the pain crawl out through the holes."

Is Conviction for Abortion Possible in Ohio?—Under this head the *Columbus Medical Journal* cites a number of cases in which abortionists failed to be convicted, and sums up the state of affairs as follows: "1. If the abortionist does his work, his victim alone being privy to it, he is safe; for if she lives, she will not inform against him, while if she dies, her statements are entirely worthless as evidence. 2. If others are privy to the act, the prosecution must prove that the fœtus was actually *living* at the time of the operation; and this, at least after 'quickening'—and even then only on the testimony of an expert making an examination at the time—is of course impossible."

A Congress of Polish Doctors and natural philosophers took place at Posen, ending on June 4th. There were three hundred present, some having come from Egypt, India, and other distant parts for the purpose. The next congress will be held at Warsaw or Lemberg.

Louisiana Doctors Asked to Wake up.—We sincerely commend the efforts of Dr. Richard H. Day, President of the Louisiana State Medical Society, to arouse the slumbering intellects of the Louisiana doctors into greater activity. "Respected confrères," he says, in a circular letter, "when contrasted with the *esprit de corps* of the medical profession in other States, and especially with the glowing enthusiasm of the late Texas State Medical Meeting in Belton, the languor and indifference of the physicians of Louisiana in all that pertains to the unity and advancement of the medical profession must be profoundly humiliating to all true lovers of the science and the art of medicine. Brothers of the medical profession wake up! start into a new and more vigorous life! Let your medical and literary attainments and capacity for usefulness be no longer hid in slothfulness, but let us begin at once and organize the regular medical practitioners of the whole State into town, parish, and district medical societies, and bring up to our next State meeting an organization and a work and a live membership that shall thrill our very hearts with joy, and place our State Society upon a solid and sure foundation." Louisiana medicine is dead indeed if, with the incitement of such an appeal and a prospective Exposition, it does not arouse itself.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Reports of Societies.

THE ACADEMY OF MEDICINE OF PARIS.

Stated Meeting, June 17, 1884.

M. A. GUÉRIN, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

AFTER the members had been called to order, the President announced that at its next meeting the Academy would resolve itself into the committee of the whole to hear the report upon the applications for corresponding membership.

M. CUSCO then exhibited a new form of

URETHRAL SOUND,

made according to his directions by M. Collin. It was partly rigid and partly elastic, and so constructed as to follow with ease the curves of the urethra.

M. LEGOUEST stated that since the last meeting of the Academy he had read an article in the *Lyon Médical*, by MM. Deperet and Boisset, on

THE MICROBE OF THE BISKRA BUTTON.

These gentlemen had also cultivated the microbe, and had injected it into a number of animals of different species, and had obtained results corresponding exactly with those recorded by M. Duclaux. In one case a slut, brought from Biskra, had the specific boil on its leg. This animal subsequently gave birth to two puppies who also had the Biskra buttons. Notwithstanding this additional testimony, M. Legouest was still somewhat skeptical as to the specific nature of the microbe found in these cases of Aleppo evil.

M. MARC SÉE desired to call the attention of the members to the excellent results obtained by

COMPRESSION IN THE TREATMENT OF HYDRARTHROSIS.

He thought it superior to the method advanced by M. Labbé at the previous meeting. He made compression by means of an ordinary Esmarch's bandage. He promised to give a more extended description of the procedure at some future meeting.

M. A. GAUTIER then read a note upon the

SYNTHESIS OF XANTHINE,

which he had succeeded in accomplishing. This was, he claimed, the first step made in the synthesis of albuminoid bodies. Xanthine differs from uric acid only in containing one atom less of oxygen.

M. COLIN, of Alfort, then read a paper upon

SEPTICÆMIA,

in which he came to the defence of the micro-organisms, claiming that it was by no means proven that the part played by them in the production of disease was so great as it was now the fashion to believe. He maintained that the experiments of M. Duclaux, described at the last meeting, were improperly conducted. The microbe, he said, is endowed with such a marvellous power of reproduction that it would be sufficient for the purposes of the experiment to inject a fraction of a drop, instead of twenty drops, as had been done.

Septicæmia, he continued, is one of those as yet imperfectly understood conditions in which the changes occurring may be due to one or several of a number of causes—microscopic organisms, septic agents, ptomaines, etc. Among certain animals, such as rabbits and birds, septicæmia could be very readily produced, while others, as dogs, oxen, and sheep, were hardly at all susceptible to the disease. The affection known as

GANGRENOUS SEPTICÆMIA

is not certainly specific in its nature. It cannot be distinguished, in animals at least, from the other forms of septicæmia. It is not proven that the virulence of the disease resides elsewhere than in the fluids of the affected organs, nor is it proven that it is transmissible by inoculation even from one animal to another of the same species. The assertions that are made concerning the carrying of the disease by instruments suppose an extreme degree of virulence which is, to say the least, very doubtful, and is not supported by experiments. The septicæmic virus, whatever it may be, is destroyed by a temperature of 212° F., and also by numerous antiseptic agents. The poison may be rendered innocuous, even after it has been deposited upon the surface of a wound, provided it be as yet unabsorbed. The difficulty, however—a difficulty which is often insuperable—is to destroy this substance once it has been absorbed and scattered through the system.

M. FOURNIER thought that the speaker was not quite just in his strictures upon M. Duclaux. There was nothing in the symptomatology of the Aleppo evil at all resembling septicæmia, and the experimenter was certainly able to recognize the latter disease, especially when he was on the lookout for it and had taken every precaution to prevent its occurrence. If the effects produced depended upon the amount of the culture fluid injected, it was strange that they should have varied so greatly according to the age of the fluid, the same number of drops being injected each time. And again, if the morbid symptoms were due to putrefaction, the results of inoculation should have become more marked in proportion to the age of the fluid. But the exact contrary obtained.

M. COLIN held to his original assertion. The presence of decomposing animal matters rendered the experiment inconclusive. If the same results were obtained by the injection of the microbes suspended in pure water, then they might justly be ascribed to the action of the micro-organisms.

M. AUGUSTE VOISIN then related the histories of five cases of

RETARDED DEVELOPMENT IN CHILDREN,

in which he had had an opportunity to study the lesions found post-mortem. Certain cerebral troubles are almost constantly associated with retarded ability to walk in young children. These are manifested by slowness in learning to talk, awkwardness in the movements of the upper extremities, especially when learning to write, incontinence of urine, malformations of the ears, etc. In every case he found a more or less complete

ATROPHY OF THE CONVOLUTIONS SURROUNDING THE FISSURE OF ROLANDO

at its upper extremity. The lesions were the same in kind and situation in each of the cases examined by him, and differed only in the degree of atrophy.

The Academy then adjourned.

TREATMENT OF GONORRHŒA BY OPEN-WIRE BOUGIES.—Dr. D. C. McVail uses a little contrivance made of three wires soldered together at one end, and bent into the shape of a sound, in the treatment of gonorrhœa. The instrument is intended to keep separate the inflamed mucous membrane of the urethra, and also to allow the discharge to drain freely away and not lie in the passage and give rise to renewed secretion. Another form has, instead of the flanged extremity, a short length of catheter-tube attached, and to that a short piece of rubber tube. The solution to be injected is introduced by a syringe, and when quite full the India-rubber tube is compressed by a spring clip, to prevent the escape of the fluid. Within from twenty to thirty minutes the injection will be almost wholly absorbed by the urethral walls, and then the clip may be detached. These instruments are well borne in the urethra, and the patient can pursue his ordinary avocations while wearing them.—*British Medical Journal.*

THE BIOLOGICAL SOCIETY OF PARIS.

Stated Meeting, June 14, 1884.

M. F. FRANCK, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE scientific work of the meeting was begun by M. ROCHEFONTAINE, who presented a communication on behalf of M. Aphanasieff upon the

TRANSFUSION OF PEPTONIZED BLOOD.

Since the chief danger in this procedure lies in the possible coagulation of the blood, and since blood containing a certain proportion of peptone loses its coagulability, the author conceived the idea of using blood thus prepared for transfusion. The experiments were made only upon animals, but the results obtained were so encouraging as to warrant the extension of the application to man when occasion should arise.

M. DASTRE remarked upon the importance of obtaining perfectly pure peptones, and also upon the accidents sometimes following the introduction of peptones into the circulation.

M. REGNARD said a few words supplementary to a previous communication that he had made concerning the

EFFECTS OF HIGH PRESSURE UPON MARINE ANIMALS.

He had determined by experiments that fish subjected to a pressure of four hundred atmospheres died from hydræmia. Some of the lower forms of marine life, such as star-fish and sea anemones, could resist a pressure of one thousand atmospheres, but died if this were exceeded.

M. VIGNAT had, at M. Regnard's suggestion, studied the changes in the tissues caused by imbibition under high pressure, and he recounted at some length these alterations as they occurred in the epithelium, tendons, nerves, muscles, and connective tissue.

M. AUBEAN spoke of the satisfactory results obtained by him in producing anæsthesia by a

MIXTURE OF AIR AND CHLOROFORM.

The experiments were made in the service of M. Péan. He had found that a mixture in the proportion of seven or eight parts of chloroform to a hundred of air gave the best results.

M. DUBOIS exhibited in this connection an

APPARATUS FOR THE INDUCTION OF ANÆSTHESIA.

It was so arranged that a mixture of air and chloroform in any desired strength could be administered.

M. LABORDE presented, in the name of M. Vigier, a communication on

ORTHOXYPHENYLSULPHUROUS ACID.

This product, which is also called by the more pronounceable name of sulpho-carbol, is destined, the speaker said, to supplant carbolic acid. It has a much less strong odor, and possesses antiseptic properties, to say the least, as great as those of carbolic acid. It enjoys the further advantage of being free from poisonous properties. It had been given to a dog weighing fifteen pounds, in the dose of two drachms per diem, with impunity.

M. REGNARD then made a few remarks upon

FERMENTATION.

At the beginning of this process there was a period of inactivity, during which the ferment, of beer, for instance, produced no effect. He had remarked that the more nearly saturated was a solution of sugar, the shorter was this period of calm. He suggested that possibly the beer ferment required some other substance to excite it to action.

After the transaction of some general business the Society adjourned.

THE MEDICAL SOCIETY OF BERLIN.

Stated Meeting, June 11, 1884.

PROFESSOR VIRCHOW, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society having been called to order by the President, HERR B. FRAENKEL presented a patient who had suffered for four years from

FACIAL SPASMS,

involving the left side. A varied treatment had been followed without success, and finally the patient was sent to Dr. Fraenkel on account of pain which she suffered in the left nostril. A mild periostitis of the nasal bone was found, which subsided again in a few days. While making an examination with the rhinoscope he found that the spasms were excited by any irritation of the nasal mucous membrane. Even touching this membrane with the sound was sufficient to induce the one-sided twitchings. The attempt was then made to cure the spasms by applications of the galvano-cautery to the mucous membrane of the nose. Even after the first application, the twitchings became less frequent and less violent. A complete cure was obtained after five applications, made especially to the middle meatus, from irritation of which part the spasms were most easily excited. The patient had been under observation for six weeks and had had no relapse.

As regards the changes observed in the mucous membrane, the speaker said that there was nothing to be seen but some redness and a very slight amount of swelling. Previous to the periostitis, the patient had never made any complaint of trouble in the nose which might indicate that this was the starting-point of the spasms. Several years ago the speaker had read a paper at a meeting of this Society upon

THE RELATION OF ASTHMA TO DISEASES OF THE NOSE,

in which he maintained that attacks of dyspnœa might be caused by a reflex action, excited by irritation of the nasal mucous membrane. Since that time considerable attention has been paid to the reflex neurosis of nasal origin. The case just presented showed the excellent results of a properly directed treatment. The patient had suffered for four years from an apparently intractable affection, which was nevertheless radically cured by five sittings with the galvano-cautery.

HERR E. HAHN then exhibited an

IMMENSE TUMOR OF THE NECK

removed from a man seventy-four years of age. It had been observed for the first time thirty years before, and was then the size of a walnut, and situated at the back of the neck over the sixth cervical vertebra. At first there was no pedicle, but as the tumor continued to grow it became pendulous and pediculated.

At the time of the operation the tumor weighed seventeen pounds and was attached by a pedicle, seven and a half inches broad and formed of integument, to the back near the fourth dorsal vertebra. The lower part of the growth reached down to the level of the fourth lumbar vertebra. The skin was unchanged and was movable over the tumor. The latter was as hard as bone in some places and softer in others. After removal it presented on section a bright yellow color, and was of the consistency of firm lard in some parts, and as hard as cartilage or bone in others. These hard portions were found to be concretions of lime salts. On the under side of the tumor the skin and subcutaneous cellular tissue presented the appearance of having been sown with minute fibromata.

Herr A. Baginsky presented a specimen of

THE BRAIN OF A CHILD,

which he exhibited as showing that it is possible, in certain cases at least, to determine the

LOCALIZATION OF CEREBRAL LESIONS

even in very young children. The little patient was but nine months old when the first symptoms appeared. The pupil of the right eye was dilated, and there was ptosis on the same side. The left eye was rotated outward, and at the same time its axis was directed somewhat downward. There was also complete paralysis of the left facial nerve. The symptoms argued against trouble at the base of the brain; for any lesion in this situation so extensive as to involve the motor oculi and facial nerves must have given rise to symptoms of meningitis, and these were completely absent. Being thus forced to the diagnosis of a central lesion, the location could be settled with tolerable certainty in the anterior portion of the pons, where the centres for the motor nerves of the eye are to be found. And since the ptosis and paralysis of the sphincter iridis were upon the right side, the lesion was probably on that side also. Further, since syphilis could be excluded, it seemed most probable that the lesion was tubercular in its character. Later there were twitchings in the left arm and leg, an inclination of the head backward and to the left, and a general curve of the body to the left side—phenomena indicative of a lesion in the right crus cerebri, as well as in the anterior portion of the pons varolii. The disease progressed steadily until the death of the child. The autopsy showed a considerable amount of fluid within the cranium, but not a trace of meningitis or miliary tuberculosis. In the right crus was found a collection of cheesy matter extending forward to the optic thalamus, and backward into and involving the anterior third of the pons. Almost the entire portion of the crus had undergone this caseous degeneration. There was a reddish brown zone surrounding the softened portion of the brain. Examination failed to show the presence of tubercle bacilli.

Herr P. Güterbock then read a paper upon

HEREDITARY SYPHILITIC JOINT DISEASES.

The author had published an article on this subject in the *Archiv für Klinische Chirurgie* for 1878, in which he had summarized all that was then known about syphilitic joint affections in young children. He now desired to supplement that article with the conclusions drawn from a further experience with the disease in question. He opposed the views of several authors, chiefly English, that syphilitic joint lesions in children were of common occurrence. He had met with but one case of hereditary syphilis out of every three hundred patients under five years of age. It is important to distinguish this form of joint disease, since the prognosis, with proper treatment, is very favorable. But, on the other hand, the chances of recovery in tubercular arthritis are very small. The author gave in detail the histories of two of his cases, one of which he treated by corrosive sublimate baths; the other by the internal administration of potassium iodide. Any operative interference in this class of diseases is usually productive of untoward results. In conclusion, he insisted upon the necessity of an early diagnosis and the prompt institution of appropriate treatment.

The Society then adjourned.

A Simple Contrivance for Making Camphor Water.—Dr. James Dunworthie, of Dobb's Ferry, sends us a bit of glass tubing in which is pushed a piece of gum camphor. This can be thrown in a bottle of water and will sink to the bottom. The glass holds the camphor in the water.

THE ROYAL IMPERIAL SOCIETY OF PHYSICIANS IN VIENNA.

Stated Meeting, June 6, 1884.

Professor v. Arlt, President, in the Chair.

(Special Report for The Medical Record.)

The paper of the evening was read by Professor Billroth. and was chiefly a collection of statistics bearing upon the operation of

EXTIRPATION OF THE KIDNEY.

This operation was performed for the first time by Simon, fifteen years ago. Since then, according to the tables prepared by Dr. Schustler, there have been 132 recorded cases of extirpation of the kidney. Of these cases, 70 recovered and 62 died, a mortality of 47 per cent. These figures were, however, the speaker maintained, misleading, if used as a basis for the prognosis of individual cases, since the success or failure of the operation in each case depended so much upon circumstances.

He then proceeded to dissect these statistics, dividing the cases into classes according to the indications for operation. In every instance in which the extirpation of the organ was, so to speak, unpremeditated—that is, when in operating for the removal of an abdominal tumor—it was found necessary, on account of adhesions, to remove the kidney as well, a fatal result was recorded.

Healthy kidneys had been removed in answer to three indications: 1. In three cases of abdominal wounds involving the kidney, the injured organ had been removed. 2. In nine cases of extirpation, on account of fistulæ of the ureter, six had died. 3. Fourteen operations for the removal of a wandering kidney have been recorded, six of which resulted fatally. The author hoped that some method might yet be devised by which the kidney could be fixed, thus avoiding the high mortality attending the operation.

The extirpation of a diseased kidney has been undertaken for suppuration (pyonephrosis, perinephritis) twenty-two times with successful result; on account of a tumor, thirty-three times with twenty deaths; for hydronephrosis, nine times with six recoveries.

The author then detailed the various steps in the two operations for extirpation of the kidney, giving his preference for the lumbar incision over laparotomy.

Dr. Jurié had removed a floating kidney successfully, after having made two futile attempts to fix it. The patient recovered, but hanged herself subsequently, being led thereto by some family troubles.

Dr. Bergmeister then exhibited a patient with

CONGENITAL DERMOID TUMORS OF THE CORNEA.

The two tumors were of a reddish yellow color, and were placed symmetrically on the outer side of the cornea of each eye, but were of unequal size. The same patient had also a

CONGENITAL CICATRIX OF THE FACE,

extending from the left corner of the mouth across the cheek to the ear. The cicatrix was somewhat sunken and lightly stretched, and presented at its outer extremity a little integumentary tumor. The latter had been cut off. This cicatrix, Dr. Bergmeister thought, was due to amniotic adhesions to the skin. There was one more point of interest about the case, and that was an

ASYMMETRY OF THE FACE.

The whole left side of the face was less developed than the right, and the left corner of the mouth was elevated, probably from contraction of the cicatrix.

Finally, Professor Rosenthal presented a patient with

BULBAR PARALYSIS,

and related his history at length. The peculiarity of the case consisted in the fact that the sclerotic atrophy o

the nuclei began in the upper half of the calamus scriptorius, and then extended gradually downward.

Professor Benedikt made some further remarks on

CRANIOMETRY,

and exhibited his instruments, and detailed the various steps of the methods of measurement used by him.

At the conclusion of this demonstration the Society adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NORTHWEST LONDON HOSPITAL—DR. JOSEPH ROGERS—TYPHOID IN SWITZERLAND—DR. COBBOLD ON TRICHINOSIS AT THE HEALTH EXHIBITION.

London, July 28, 1884.

An event which may be fraught with grave consequences to the management of hospitals has just occurred and has excited no little attention. The scene of action is at one of the younger hospitals—the Northwest London Hospital. The committee of this institution have thought fit to dismiss one of the surgeons without assigning any reason. The staff have resented this treatment by resigning almost *en masse*. They have at the same time forwarded a written protest. It appears that the management is vested in three ladies, one of whom founded the hospital. Of the other two one is also acting as matron. The recent appointments to the acting staff were made by these ladies without consulting the medical officers of the hospital, and the recent dismissal of one of the surgeons has been effected in the same manner. There is a charming frankness in the way in which it is generally admitted that these three ladies have really appointed the staff. Such oligarchical arrangements are not unknown in other hospitals than that in point, but are not usually so openly acknowledged. Frequently, though, appointments to smaller hospitals are really made by one individual—often the founder—who quietly tells the committee what to do.

On Tuesday last a testimonial was presented to Dr. Joseph Rogers, the well-known Poor-law medical officer and sanitary reformer. The presentation took the form of a piece of plate and a cheque for £150, and the several speakers referred to Dr. Joseph Rogers' well-known services to sanitary science and reform.

Typhoid fever is still prevalent in Switzerland, especially around Geneva and Zurich. At this season of the year, when so many tourists are going to Switzerland, the health of that country cannot but be of interest to British practitioners, who, but for the prevalence of typhoid, might now be sending their patients there. The Swiss authorities have endeavored to make as light as possible of the matter, but in Zurich and Geneva twenty-six deaths from typhoid occurred during the four weeks ending June 14th.

Perhaps the best lecture as yet delivered at the Health Exhibition, has been that just given by Dr. Cobbold on Parasites. A large portion of the lecture was devoted to the subject of trichina. The life-history of the parasite was described and epidemics of trichinosis referred to. Dr. Cobbold said that the only genuine instance of trichinosis diagnosed in England, was that in Cumberland, described by Dr. Dickinson in the Cantor Lectures. Several persons were affected in this outbreak. All other alleged outbreaks were misinterpretations of the facts observed. A great number of little worms living in various animals had been described as trichinæ by persons not familiar with parasites, and to this was due the periodical "scares" got up by newspapers. As to these "scares," Dr. Cobbold remarked that ignorant writers in the daily papers seemed to take pleasure in creating them. The recent attempt to get up a "mackerel-scare" fell rather flat. In regard to preventive measures, the lecturer said he thought the question as to the temperature required to kill the trichinæ had been set at rest by the labors of Perroncito, who found that cooking meat at 120° F. was sufficient to destroy the parasites. M. Colin had shown that two or three weeks salting was sufficient to kill them in the superficial parts of the flesh salted, but the deeper parts might not be reached for a couple of months.

THE FEEDING OF INFANTS, AND HOW TO PREPARE PEPTONIZED MILK.

To the Editor of The Medical Record.

Sir: Since the publication of your editorial on the feeding of infants, I am receiving letters from physicians asking how to peptonize milk. I am not surprised at the interest awakened in the subject at this season, when so many infants are sick from improper diet. Most inquirers live at a distance. New York physicians are, I think, with few exceptions, familiar with the process. The advice that I give to my families as regards the preparation of milk is as follows: Scald the milk when it arrives in the morning, and then place it on ice. Do not peptonize more than half a pint to one pint at a time; and what the infant does not take immediately afterward, should be kept upon ice and surrounded by ice for the second feeding.

The peptonizing process is as follows: Mix a powder consisting of five grammes of Fairchild's extractum pancreatis, and ten grains of sodium bicarbonate in one gill of tepid water. Add this gill to one pint of tepid milk, and place it in a bowl in a pan of water maintained at a temperature of 100° or a little over. In one hour or less time, the process is completed. Too much peptonizing renders the milk bitter. Some milk is sufficiently digested in thirty or forty minutes, and the nurse who prepares it should occasionally taste it after the first twenty minutes, and remove it from the pan of warm water before the hour has expired. If the least bitterness be noticed, the pancreatic ferments are destroyed by boiling, and rendered inactive; but not destroyed by a temperature near that of ice. We do not wish to destroy the ferments but wish to have them active in the stomach of the infant. Hence, the direction to place the peptonized milk on ice, instead of boiling it. The object is to prepare for infants a food which will resemble as closely as possible human milk in nutritive properties and digestibility, and peptonized cow's milk appears to be the nearest approach to it yet obtained.

The great importance of the subject induces me to send to you for publicat on the following private letter from Professor Leeds, as perhaps it may aid in saving life. It is known to most of your readers that Professor Leeds has made more analyses of infants' foods than any other chemist, and that no one is better able to give advice in dietetics from a chemical standpoint than he. The letter relates to his remarks on infant feeding at the meeting of the County Medical Association on June 16, 1884.

"Sir: The formulæ which I ventured to suggest for the preparation of humanized cow's milk was as follows: 1 gill of cow's milk, fresh and unskimmed, 1 gill of water, 2 tablespoonfuls of rich cream, 200 grains of milk sugar, 1¼ grams of extractum pancreatis, 4 grammes of sodium bicarbonate. Put this in a nursing-bottle, place the bottle in water made so warm that the whole hand cannot be held in it without pain longer than one minute. Keep the milk at this temperature exactly twenty minutes. The milk should be prepared just before using. . . . Yours truly,

"Albert R. Leeds."

The summer season, when infantile diarrhœa is so prevalent, affords the opportunity for testing peptonized milk, and it is my opinion, from a considerable number

of observations, that it is the safest and best substitute for breast milk. Moreover, it appears to be good food for children in the second and third year, who are sick or have feeble digestion. The profession are indebted to the Messrs. Fairchild for a cheap and reliable extractum pancreatis. Yours, J. Lewis Smith, M.D.

New York, July 11, 1884.

CONCERNING THE CONDUCT OF THE EXAMINERS OF THE ROYAL COLLEGE OF SURGEONS, ENGLAND.

To the Editor of The Medical Record.

Sir: The statements contained in your London correspondent's letter of May 24th, respecting the examiners of the Royal College of Surgeons, are incredible. This insinuation that many of them are not gentlemen is grossly unfair, but is a little vague, no one having yet hit upon a quite satisfactory definition of that honorable title. But it is certain that all the examiners have been and are men of good professional standing and attainments. It is quite incredible that a candidate could be "dragged around the room by his coat" when we remember that all the examiners and examinees are in one, not very large, room, containing four tables and as many sets of examiners. As to the other story of the examiner who swore at the candidate and kicked up his heels, that is equally unlikely. I may say that complaints have often been made of the examinations at the College and even of the behavior of examiners, but this has never referred to anything but harshness of manner or sarcasm, which certainly are not desirable in an examiner. Your correspondent's tales are merely high-flavored articles for exportation and would only be laughed at here.

Yours faithfully, Robert Saundby.

7 Newhall Street, Birmingham, Eng., June 23, 1884.

THE TREATMENT OF TAPEWORM—PELLETIERINE.

To the Editor of The Medical Record.

Sir: Having noticed several several inquiries in the columns of your journal recently in regard to the most successful method of disposing of tapeworm, and having treated a number of cases with the remedy which heads this article, I have concluded to give the profession the benefit of my experience.

Few practitioners of large experience have escaped the annoyances spoken of by your correspondents. In a practice extending over twenty-four years I have treated about twenty cases, some of which have been very perplexing, especially the *tænia saginati*, or beef-worm. Almost any of the remedies ordinarily used will destroy the *tænia solium* or pork-worm. The popular idea that the former, or *unarmed* variety, is the easiest to destroy is erroneous. I have succeeded with almost all the remedies which I have tried in destroying the solium, but only occasionally have I been successful in expelling the saginati entire with anything except the pelletierine. The prevalent opinion that the solium is the more prevalent of the two worms is also a mistake as I have met about three of the former to one of the latter.

Case I.—On July 2, 1883, I administered pelletierine to a vigorous healthy male patient, forty-five years of age. He had been afflicted with the worm for fifteen months. He had taken June 25, 1882, fluid extract kamela, and passed about twenty-five feet of the worm, but no head. In about three months the ripe segments began to pass again. At this time he took fluid extract male-fern with a result similar to the kamela. In December following, he took kousso with the same result, passing about twenty feet of the parasite. In March following, a mixture of male-fern and kamela was given the patient with the usual result. On July 1, 1883, twenty grains of Merk's tannate of pelletierine was given. No part of the worm was dislodged, but upon the following day, at 5 o'clock A.M., one ounce of Tanret's pelletierine was administered, followed by four ounces of infusion of senna, and at 7 A.M. the parasite, unbroken, was passed, to the great relief of the patient.

Case II.—Wife of Case I., contracted the disease at the same time, both being afflicted with the tænia saginati. Patient had similar treatment with no better results. Pelletierine was administered July 4th, at 3 o'clock A.M., followed in one hour with the infusion of senna. Parasite passed entire at 6 o'clock A.M., making the entire family happy.

Case III.—Was that of a German, aged fifty-seven. Had been afflicted five years. Had taken medicine several times without success. Was unable to ascertain what remedies had been used. Two years before consulting me had an attack of typhoid fever, which lasted six weeks, during which time several feet of the worm passed. May 21, 1883, gave him fluid extract kamela, after the usual preparations. Passed about fifteen feet of the parasite, but no head. Three months afterward the patient returned for further treatment. Gave him pelletierine, but a portion of it was lost by vomiting, repeated the dose in three hours, followed by one ounce of compound tincture of jalap. Worm passed unbroken, in one hour after the last dose.

Case IV.—Male, aged thirty-four; carpenter by occupation; had been passing proglottides about a month. Had taken medicine from a physician which purged him violently, but with no result. Gave him pelletierine after the usual preliminary treatment, following it with compound tincture of jalap, which did not move bowels for nearly six hours. The parasite passed unbroken notwithstanding the delay.

Case V.—Was a young man, aged twenty-one; student, who had been afflicted over two years, but had taken no treatment. Gave medicine in the usual way, with a perfect success.

Case VI.—Was a young lady, aged fifteen. Had been afflicted two years. Had taken kamela, kousso, and male-fern without success, passing several feet of the worm at each administration, but no head. I gave her the pelletierine in the usual way, with the same success as in the other cases.

All the preceding cases were of the tænia saginati. Perhaps one reason why I have met the saginati oftener than the solium is because I practise in a blue-grass, beef-producing region, and where a majority of the inhabitants eat their beef underdone.

No symptoms were present in any of my cases which would indicate the presence of tapeworm, except the passing of the ripe segments. The patients had none of the symptoms laid down in the books. They all enjoyed vigorous health, and complained of nothing save the annoyance caused by passing the proglottides, which was liable to occur at any time without warning.

Pelletierine is the alkaloid of the pomegranate bark, and is manufactured by Charles Tanret, 64 Rue de Rampart, Paris, France. Tanret is a student of Pelletier, who first succeeded in extracting the alkaloids from the cinchona bark. A desire to honor the name of his illustrious preceptor is sufficient cause for the name of the alkaloid.

It is a pleasant, safe, and speedy remedy. When stirred in a glass of sweetened water it is as pleasant to the taste as a glass of lemonade. It is followed in a few minutes by a transient dizziness or vertigo, which in some of my cases was quite severe. It should be followed in half or three-quarters of an hour by a brisk cathartic—compound tincture of jalap or infusion of senna. A neighboring practitioner gave the cathartic before administering the remedy, and the worm was expelled in less than an hour after taking the pelletierine, but it was a tænia solium. G. C. Smythe, M.D.

Greencastle, Ind., June 24, 1884.

To the Editor of The Medical Record.

Sir: In the Medical Record of June 21st, Dr. Thomas Wilde offers a prescription for the removal of tape-worm, which has so great a similarity to a mode of treatment used by myself for several years with such unvarying success that I am induced to offer it to you as an appendix to Dr. Wilde's article. It has, however, this advantage, that the time required to produce its effect is only about twelve hours, instead of being drawn out for a week. The formula, I believe, originated with Dr. A. J. Shafish, of Washington, D. C., and was published over the signature of Dr. Trumbull in the *Medical and Surgical Reporter*. My attention was called to it by Mr. Byron Stedman, a most excellent pharmacist of this city, who obtained it from the records of the Brooklyn Dispensary, with which institution he was at one time connected, who prepares it with more than ordinary skill. During the past year I have treated eleven cases, in each and every case the entire worm has been expelled at once. In the majority of the cases the head has been discovered, while in those in which it was not found the tenuity of the cephalic extremity left no doubt in my mind but that the head had passed away and been lost among the fecal discharges. At any rate, the non-return of the parasite in those cases in which the head was not found proves the destruction of the unwelcome tenant. I have used it in delicate women and children, and beyond a temporary prostration have witnessed no bad effects. My usual course is to ask the patient when he can conveniently attend to the removal, and setting a day, making no change in his diet whatever, give at bed-time half an ounce of Rochelle salts. The following morning at about ten o'clock—all food having been omitted—I give the following, prepared as I shall state:

℞. Cort. rad. pomegranate..... ℥ ss.
Pumpkin seeds..... ℥ j.
Kernel of ergot..... ℥ ss.
Ethereal ext. male-fern..... f℥ j.
Gum arabic..... ℥ ij.
Croton oil..... gtt. ij.
Aquæ..... f℥ vj.
M.

In about two hours the worm is expelled. The success of this mode has been unvarying. The foregoing draught is intensely bitter, and tends to nauseate, but by directing the patient to drink it quickly and lie down immediately, the tendency to vomit is arrested. After the worm is discharged, I order a strong milk-punch, and if the bowels seem irritable or are painful, a dose of opium or morphia removes the trouble. In a day or two an iron tonic is given.

In the preparation of the anthelmintic bruise the bark, pumpkin seeds, and ergot in a mortar to moderately fine powder, heat for half an hour in the water in a water-bath, strain, and on the residuum pour enough hot water and strain with pressure to bring the quantity of strained fluid up to six ounces. Put the oil into the gum arabic, add the male-fern—emulsionize the whole. With care a fine emulsion is produced.

I am looking for a remedy against "pin-worms" which shall prove as successful and prompt as is the one I have given you against the tænia. H. Lyle Smith, M.D.

Hudson, N. Y., June 23, 1884.

To the Editor of The Medical Record.

Sir: In response to a request of a subscriber for the treatment of tapeworm I will say that I once saw in an old number of *Braithwaite's Retrospect* an item advising the use of creasote in persistent cases, since that I have used that agent after all others had failed, with invariably successful results. I have given one drop in an emulsion of acacia three times daily for two days, then increased to two drops three times daily for two days, then to three drops for two or three days, when the head has universally come away. Finley Ellingwood, M.D.

Manteno, Ill., June 17, 1884.

To the Editor of The Medical Record.

Sir: For the benefit of your subscriber who seeks information upon the best treatment of tapeworm, I would suggest to him the use of Tanret's pelletierine. I have used the remedy in six cases, five of them being successful.

Fougera & Co., New York City, are the agents for Tanret's pelletierine in this country.

Yours, very respectfully, H. Wilfert, M.D.

Cincinnati, June 16, 1884.

To the Editor of The Medical Record.

Sir: In reply to a request of one of your subscribers (Medical Record, p. 682, June 14, 1884), and for the information of those interested in the subject, a mode of treatment for tapeworm is given below which has proved in my hands to be better than any other, and has have given most satisfactory results. A reliable remedy for the relief of tapeworm is a valuable addition to the therapeutical knowledge of every general practitioner, for whatever the opinion of medical minds may be about the severity of disturbances caused directly by the presence of parasites in the alimentary canal, it cannot be disputed that laymen attribute great importance to their presence. I have seen a large number of cases of tapeworm, and have given a fair trial to the variety of remedies which are generally administered in such cases, including the infusion of pomegranate root, as recommended by Dr. Thomas Wilde (Medical Record, May 31, 1884). The principal objection to the use of the latter is its unpleasant taste and the large amount of fluid which has to be taken; in a number of cases where the pomegranate infusion had been used it produced violent emesis, and some patients were unable to retain it, even in small doses. In four cases out of fifteen the entire worm had been expelled and the head found, but almost all the patients complained of the harsh treatment.

The treatment which has been followed by the best results is a simple one, any reliable apothecary can prepare the prescription, and patients will take the medicine without difficulty. Although it is not essential to have the patient fast for any length of time, still it is advisable to allow only moderately of food during the afternoon and evening of the first day, and to abstain from food entirely while taking the medicine in the morning from 8 to 10 A.M. The following are the prescriptions to be given as directed:

℞. Hydr. chlor. mite..... gr. x.
Pulv. jalapæ..... ℥ ss.
Pulv. aromat..... gr. x.
M. Ft. pulv. No. 2.

S.—Take one powder at 4 P.M. and the other one at bed-time.

℞. Ext. male-fern ether..... ℥ iij.
Ext. sennæ fld..... ℥ iij.
Ext. hyoscyami fld.,
Tr. menth. pip.....aā ℥ ss.
M. Ft. mist.

S.—Take one teaspoonful (good sized) every half hour—to commence at 8 A.M. the day after the powders have been taken.

The use of hydr. chlor. mite as a preparatory remedy has been suggested by Dr. R. Kuchenmeister in Dresden.

Paul H. Kretschmar, M.D.

Brooklyn, N. Y.

Nux Vomica as a Galactagogue. — Dr. Posada Arango speaks very highly of the good effect of nux vomica as a stimulant to the secretion of milk. He gives ten drops of the tincture three times a day, and explains its galactagogue properties by its action on the mammary gland, exciting it to secretion, and by its stimulating action on the stomach facilitating digestion. He recommends strychnia in recent cases of complete suppression of the secretion.—*London Medical Record.*

THE QUESTION OF THE FLORIDA CLIMATE.

To the Editor of The Medical Record.

Sir: On April 26th last you published in The Record a letter from Dr. Boyland, of Baltimore, upon "Florida as a Health Resort." As some of his statements were so opposite to my observations, I felt like rushing into print and criticism of the Doctor's paper. But as it is now over two years since I was last in Florida, and not knowing what wonderful changes might have occurred there meantime, I immediately wrote my friend Dr. Phillips, of Gainesville, Fla., for a few statistics. Unavoidable accident delayed his answer and consequently this of mine. His letter is now before me, but as time cures almost every curable thing, my first impulse to criticise shall be modified and confined to a few items relative to the respective advantages as sanitariums of Gainesville and Cedar Key (not "Keys"). Dr. Boyland disparages Gainesville by complaining of its level surface and defective drainage, also on account of the vast number of consumptives whom he seems to believe do congregate there in shoals and nations, and the almost daily deaths among whom (as he says) exert a "deleterious effect upon other and non-phthisical cases." Bad! bad enough, if true, but Dr. Phillips says (and I will vouch for his truthfulness) "there were not to exceed six cases of deaths among the visitors at Gainesville from November, 1883, to May, 1884."

How about "the almost daily deaths" reported by Dr. Boyland? As to the level surface and defective drainage, I can speak for myself. I say the ground is rolling, that most of the streams are situated in deep ravines, and the currents lively. I say further that Gainesville is drained by a natural sink, about two miles south of the town. The streams of the surrounding districts pour down the great throat of this inlet to the vast cavernous passage below the limestone stratum; where the water again comes to the surface no one knows, but from the direction of the line of depressions, marking the course of the subterranean stream, it probably runs north and directly under Gainesville, for about two miles north of the town is one of these depressions (and the largest of them all) where one can go down dry-shod from the pine-covered sand above, over one hundred feet to the coral rock bed or backbone of the State. So much for the level surface and want of drainage of Gainesville.

Now, as the Doctor recommends Cedar Key to those who desire a seaboard resort, I must conjecture that his acquaintance with that city is secondary, also that his informant (if informant he had) does not eliminate truth freely.

The drainage of Cedar Key is largely into the wells, the air is redolent of bilge-water and putrid things. With the periodic winds, quotidian fogs, perennial fleas, nocturnal mosquitoes, with nothing to please the eye, everything to offend the nose, and not one drop of clean well-water to cool the mouth, I would recommend Cedar Key to no one, except a scavenger, and him one of about the nine hundred and ninety-ninth "stage." As a sanitarium I prefer Gainesville to any other town in Florida known to me; Cedar Key I would place last in the fullest catalogue.

Wm. B. Bradner, M.D.

Warwick, N. Y., May 26, 1884.

SHALL OFFICERS OF THE ARMY ENGAGE IN PRIVATE PRACTICE.

To the Editor of The Medical Record.

Sir: Some time ago I wrote to the Surgeon-General of the Army for information respecting some points of practical importance to physicians, and in reply received word that not only was there no rule or regulation preventing post surgeons from engaging in general practice, but that it was his custom to advise post surgeons to get all the practice they could outside, *so that they might not grow rusty*.

As this seems to me anything but a fair and proper course to pursue; and as an earnest protest on my part has received absolutely no notice whatsoever, I wish through your columns to inform those physicians who are so unfortunate as to live where army surgeons are stationed, of just what they may reasonably expect. If there is no impropriety, not to use a harsher term, in attempting to secure outside practice while drawing full and presumably adequate pay from the Government, then I must confess myself so mentally obtuse as not to perceive it.

In the first place it is *unfair* competition. The army surgeon is backed by an assured salary. The office he occupies and the horse and buggy he uses are in part paid for by the very physicians against whom he comes in competition. To the military medical mind this may seem fair and honorable. To the civilian, however, it certainly does not.

In the second place, the fear *that the army surgeons may grow rusty* affords no manner of excuse for pirating outside of the post. If there is not enough for the surgeons in the army to do, then cut down the number; or else give them more soldiers to look after. It is the Government's fault that there are too many surgeons for the number of soldiers. Let the Government remedy that and not advise their subordinates to encroach on ground not legitimately their own. Have civil practitioners no rights as opposed to salaried Government officers? Were there a dearth of local physicians an army surgeon might be excused for answering calls in emergencies. Such conditions, however, do not obtain here in the East.

I hesitate to believe that the majority of army surgeons would follow any such advice as has emanated from the Surgeon-General, having been informed by gentlemen of the army that practising outside of posts has not been customary in the past, except in such places where physicians were few and far between, as in the far West; and moreover such practice has always been regarded as not strictly fair and honorable, except under the exceptional conditions just mentioned.

Very truly yours,

John G. Stanton, M.D.

New London, Conn.,
July 8, 1884.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 6 to July 12, 1884.

Perin, Glover. To be Assistant Surgeon-General, with rank of Colonel, promotion to date from July 2, 1884.

Smith, Andrew K. To be Surgeon, with rank of Lieutenant-Colonel, promotion to date from July 2, 1884.

Middleton, Passmore. To be Surgeon, with rank of Major, promotion to date from July 2, 1884.

Clements, B. A., Major and Surgeon. Also directed to relieve Surgeon J. P. Wright of his duties as Acting Medical Director, Department of the Missouri. S. O. 138, par. 1, Headquarters Department of Missouri, July 8, 1884.

Promotions.—To be Assistant Surgeons, with the rank of Captain after five years' service, in accordance with the Act of Congress of June 23, 1874. Assistant Surgeons John J. Kane, John M. Banister, Aaron H. Appel, Charles Richard, W. Fitzhugh Carter, June 3, 1884.

Birmingham, H. P., First Lieutenant and Assistant Surgeon. From Fort Bayard, N. M., to Fort Bliss, Texas. S. O. 137, par. 3, Headquarters Department of the Missouri, July 3, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending July 12, 1884.

LUMSDEN, G. P., Passed Assistant Surgeon. Ordered to U. S. S. Wyandotte.

PERSONS, R. C., Passed Assistant Surgeon. Detached from U. S. S. Wyandotte and placed on waiting orders.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, April 1 to June 30, 1884.

BAILHACHE, P. H., Surgeon. Detailed as chairman of Board to examine candidate for appointment into the Revenue Marine Service, May 17, 1884.

VANSANT, JOHN, Surgeon. To proceed to Empire City, Oregon, as Inspector, April 2, 1884.

HUTTON, W. H. H., Surgeon. Granted leave of absence for twenty-five days, May 14 and June 9, 1884.

MILLER, T. W., Surgeon. Granted leave of absence to attend the meeting of the American Medical Association, May 1. To proceed to Pittsburg, Pa., Ashtabula, O., Buffalo, N. Y., and Detroit, Mich., as Inspector, May 10, 1884.

WYMAN, WALTER, Surgeon. To proceed to Crisfield, Md., as Inspector, April 11, 1884. Detailed as president of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884. To examine cadet-graduates Revenue Marine Service as to physical qualifications, May 31, 1884. Detailed as member of Commission to inspect United States buildings at Quarantine Station on the Delaware River, June 16, 1884. Detailed to represent the Marine Hospital Service as Delegate to the American Medical Association, April 17, 1884.

AUSTIN, H. W., Surgeon. Granted leave of absence to attend the meeting of the American Medical Asssociation, May 2, 1884.

GASSAWAY, J. M., Surgeon. When relieved by Passed Assistant Surgeon Mead, to proceed to Portland, Me., and assume charge of the Service, April 16, 1884. Granted leave of absence for thirty days, May 28, 1884.

STONER, G. W., Passed Assistant Surgeon. When relieved by Surgeon Gassaway, to proceed to Cairo, Ill., and assume charge of the Service, April 16, 1884. When relieved by Surgeon Gassaway, to report in person to the Surgeon-General, June 20, 1884.

IRWIN, FAIRFAX, Passed Assistant Surgeon. Granted leave of absence for twenty-one days, June 19, 1884.

MEAD, F. W., Passed Assistant Surgeon. When relieved by Assistant Surgeon Devan, to proceed to Philadelphia, Pa., and assume charge of the Service, April 16, 1884. Detailed as recorder of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884.

CARTER, H. R., Passed Assistant Surgeon. To inspect unserviceable property at the San Francisco Hospital, May 24, 1884.

WHEELER, W. A., Passed Assistant Surgeon. To inspect unserviceable property at the Chicago Hospital, May 24, 1884.

BENSON, J. A., Passed Assistant Surgeon. Granted leave of absence for thirty days, April 14, 1884. When relieved by Passed Assistant Surgeon Stoner, to report to him for temporary duty, May 19, 1884.

BANKS, C. E., Passed Assistant Surgeon. Detailed as member of Board to examine physically candidate for appointment into the Revenue Marine Service, May 17, 1884. To inspect unserviceable property at Baltimore, Md., New York, N. Y., and Boston, Mass., May 26 and June 2, 1884.

BENNETT, P. H., Assistant Surgeon. Granted leave of absence for twenty days, June 28, 1884.

DEVAN, S. C., Assistant Surgeon. To proceed to Port Townsend, W. T., relieve Passed Assistant Surgeon Mead, and assume charge of the Service, April 14, 1884.

URQUHART, F. M., Assistant Surgeon. Granted leave of absence for thirty days, May 22, 1884.

YEMANS, H. W., Assistant Surgeon. To report to Captain M. A. Healey for duty as Medical Officer during cruise of Revenue Cutter Corwin, April 16, 1884.

GLENNAN, A. H., Assistant Surgeon. To proceed to Mobile, Ala., for temporary duty during sickness of Passed Assistant Surgeon Goldsborough, June 17, 1884.

BROOKS, STEPHEN D., M.D., Massachusetts, having passed the examination required by the Regulations, was appointed an Assistant Surgeon by the Secretary of the Treasury, May 15, 1884. (Dr. Brooks had previously served as an Acting Assistant Surgeon from March, 1883, to May, 1884).

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 12, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
July 5, 1884.....	3	6	27	3	156	41	0	0
July 12, 1884.....	2	8	55	4	187	31	0	0
Deaths.								
July 5, 1884.....	0	2	12	3	30	20	0	0
July 12, 1884.....	0	3	14	3	27	18	0	0

A CASE OF SUCCESSFUL REPLANTATION OF A TOOTH is recorded in the *Weekly Medical Review* by Dr. A. B. Barnette. He writes that he extracted the tooth, cleaned the cavity, washed the tooth well and put it back. Inside of a month it was firm and he had it filled.

THE CHOLERA GERM AND THE LOCAL AND TIME FACTORS.—Professor von Pettenkofer, of Munich, has written an article in the *Neuesten Nachrichten* in which he shows that a bacillus or germ is not alone sufficient to explain the causation and transmission of cholera. There must be certain conditions of season and soil which favor its development. These he calls the "local and time factors."

F. HEBRA'S PRESCRIPTION FOR BALDNESS.—℞. Tinct. macis, 5 grammes; olei dulcis, 50 grammes. M.

YVON'S PARALDEHYDE ELIXIR FOR INSOMNIA.—℞. Paraldehyde, 10 grammes; alcohol at 90°, 40 grammes; tinct. vanillæ, 2 grammes; aquæ, 30 grammes; syr. simpl., 60 grammes. M. Dose ʒ j. to ʒ ij.

REMOVAL OF A WANDERING SPLEEN.—According to an account published in the *American Medical Journal* of July, 1884, Dr. E. Younkin, of St. Louis, has successfully removed a spleen, which had committed the offence of being dislocated and causing distressing pains. The organ was, before removal, two or three times larger than normal. After removal its parenchyma was found to be healthy. The patient was a married woman, aged thirty-two, of slight build, and was in tolerably good health.

THE LAST FORM OF MERCURY recommended for medicinal use is the hydrargyrum tannicum oxydulatum, which has been prepared in the laboratory of Professor Ludwig, of Vienna. It is a greenish, tasteless powder. Dose, 0.1 gramme.

SOME REMARKS ON AFFECTIONS OF THE HEART.

BY J. MILNER FOTHERGILL, M.D. EDIN., HON. M.D. RUSH MED. COLL., ILL.

ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

IV.

CARDIAC NEUROSES.

WHEN a patient presents himself, and still more herself, before a doctor at first-hand, complaining of the heart, it is all Buckingham Palace to a sentry-box the case is one of a cardiac neurosis, and not organic disease. It is some outcome of the latter, as shortness of breath, for instance, which leads the subject to the doctor's office when the case is one of organic disease. Then, when the patient complains of pain at or near the heart, remember disease of the heart does not produce pain. Angina pectoris is the only pain linked with disease of the heart or arteries. You can at once say, "Pain has nothing to do with heart disease." The patient may have some heart trouble as a coincident matter; but, if so, this has no relation to the pain complained of. But however clear you may be about the matter yourself, you will find it no easy matter to convince the patient. Having laid down these two broad rules, the different cardiac neuroses may now be sketched in outline.

First comes palpitation. Palpitation linked with effort is usually muscular adynamy, and points to the heart as a muscle. Palpitation coming on at other times than when effort is made points either to vaso-motor disturbance (gouty), or is neurosal. When a lady is wakened up in the night with her heart beating violently, and yet now and again halts, as if it was going to stop, she is naturally very much alarmed. And yet usually she need not be alarmed. Such an experience is common with women at the menopause; and there may or may not be an asthenic condition of the heart-wall present. There may be no gout in the case; often there is. Very often in such cases there is a weak state of the heart-wall which requires attending to by appropriate measures. In some cases the attacks are due to some derangement in the innervation of the heart, connected with the accelerator fibres of the vagus. A start will cause palpitation in many persons, and especially females liable thereto. The sexual act will not uncommonly set up violent palpitation, or continence may bring on paroxysms of palpitation, relieved by intercourse. Indulgence in tea, and to a less extent in coffee, commonly leads to a condition of the heart where palpitation is experienced on slight causes. In exophthalmic goitre (Basedow's disease) a violent action of the heart is one of its main features. In chorea tumultuous action of the heart is usually present. But among all these conditions palpitation produced by effort is what puts you on the *qui vive* for "disease" as compared to "disorder" of the heart.

Then palpitation may be set up by far-away irritation. Botkin tells of a case where it was set up by a floating kidney. It is common with a misplaced womb, and disappears when the uterus is restored to its normal position. I have seen it linked with prostatic trouble, and also with anal eczema. When paroxysms of palpitation come on without obvious relationship, always institute a careful search; if you can find something, and put that something right, you will usually find the palpitation take its departure.

There is one form of palpitation which has such distinct relations, and is so commonly met with (when the doctor has learned to see it), that it deserves a few words. It is ovarian in its origin. The patient, usually a woman of child-bearing age, complains of more or fewer of the following symptoms, sometimes one being more prominent than the other: She has pain in her side with palpitation. She has vertical headache, with sense of weight and lowness of spirits, and readily weeps. She has nausea, indigestion, and often vomits her food: yet her tongue is clean (this is "clean-tongued" dyspepsia). She may be said to have inflammation of the stomach, and her friends are gravely alarmed about her; and every medical man of experience could relate such cases. She has leucorrhœa and often menorrhagia, with a large, heavy uterus. She cannot hold her water properly, and spasm is readily and easily produced (the centres for the bladder and the reproductive organs lie near together in the cord, and are therefore affected by the same cause). Beyond this the patient has times of heat, itching, and dryness at the seat and in the vagina. In well-marked cases all these symptoms are present. The cause of all these linked phenomena is an irritable ovary—when hunted down. Usually there is pain on defecation if the ovary lies over the bowels; if in front, pain in making water. Usually the ovary can be found swollen, and exquisitely sensitive to the touch. The sexual act becomes impossible from the contact of the glans penis with the tender ovary in many cases. Pressure over the ovary makes the patient feel deadly sick, and as if she would faint, or fall in a swoon. Her sensations are reflected on her face. This is a malady with distinct and unusually well-marked features, yet it has not found its way into our text-books. It is common enough to well repay study; and in a well-marked case, when symptom after symptom, into the arcana of her most private sensations, is asked after, the woman stands as if in the presence of a magician. Such apparently widely separated phenomena apparently have no connection with each other; yet their causation is identical, viz., a troublesome ovary. Waves of nerve-irritation set up in the ovary travel along different nerve-fibres, and find varied terminations. In one case they set up forcible contractions in the stomach, in another they are felt in the terminal fibres of the intercostal nerves as gusts of neuralgic pain. In all they keep the uterus in a state of turgescence, and in most there is leucorrhœa and heavy menstrual losses. Slowly, gradually, step by step, this Proteus revealed itself to me on patient persistent attention to it. Those to whom I have shown a typical case never forget it. Whether an equally vivid impression can be made by a mere description of the case is another matter. It requires the patient to be there to make it believable! with her present, conviction is unavoidable: without her, it looks—well, "like a traveller's tale." Such cases are very common. They do not readily yield to treatment, but a blister over the offending ovary, especially when the menstrual period is due, bromides and laxatives, usually in time produce the desired effect. The most marked case which ever came under my notice was that of a lady whose ovaries had been forced down on each side in front of her bladder by obstinate constipation in youth, and been

pinned there by adhesions. She was barren, and incurable, it is needless to say.

Then there are hearts which do not exactly palpitate, but beat tumultuously always, with paroxysms of true palpitation at intervals; much like the heart in cases of Graves' or Basedow's diseases. Like all disorders of the heart these cases yield but slowly to treatment; and my impression is strong that in cardiac neuroses belladonna is more useful than digitalis. I may remark that the effect of belladonna (administered internally) upon the pupil is so fitful and capricious as to form no guide to its use; and still more its disuse!

Dryness of throat and impairment of vision are more to be relied upon; still the drug need not be given up even for them.

Then there is the condition of "irritable heart," first described by DaCosta, a mixture of neurosis with atony, unfitting the owner of it for hard work; requiring rest for its cure, and patience too. It is most common in my experience among doctors of sympathetic temperament, hard-workers, who carry some of their patients' cares; good fellows who take their professional cares to bed with them—a practice Clifford Allbutt condemned. The immediate cause of the oncome is usually some extra demand involving broken rest, and then the heart becomes irritable and unequal to the demand upon it. Rest is an essential factor in the treatment of such cases, which get well, but only very slowly. It does not appear, from my experience, that the irritable heart ever passes on to structural change; further experience may not corroborate this opinion, but so far it holds good.

Then comes the disturbances of the heart's rhythm, intermittency and irregularity. Irregularity is, as all know, connected with a dilated heart, especially when combined with a mitral lesion. But intermittency may be a mere trick, as when a hale, old North Country woman observed "the tick of her heart had gone wrong." It is not uncommon as a distinct halt in the heart, at varying intervals, sometimes at long intervals, sometimes frequent, in elderly persons, unaccompanied by any evidences of real mischief afoot. At other times it is found with senile changes, and as the muscular wall of the heart is no longer well-fed, so some defective nutrition in the cardiac ganglia may affect the rhythm. When found with hard arteries and a feebly acting ventricle, where a number of the ventricular contractions fail to produce an impression on the radial pulse, then it is at once suggestive and significant. But frequently intermittency is found in young healthy subjects, who feel no inconvenience therefrom unless they are either medical men themselves, or have consulted some one. Diseases of the heart, other than valvular lesions, are so imperfectly taught in the usual hospital career, that most men have but hazy views of cardiac maladies, and consequently the doctor falls back on what he knows, or rather guesses, that there is something serious, and he will not be caught napping in his estimate of the gravity of the case. Cases rejected for insurance, cases rejected for the services, cases where some one had applied a stethoscope without the requisite knowledge to wield it wisely, and so taken alarm and communicated it to the patient, come constantly under my notice; and the apprehensions of the patient can usually be set at rest. There seems no *raison d'etre* for this arythmic condition in many cases.

Then again there is the intermittency so well and ably described by Dr. B. W. Richardson, F.R.S., which dates from some definite time. A shipwreck, some intense emotion, or other exciting cause, and the action of the heart is disturbed. A marked instance of this came under my notice some time ago in the person of a Canadian store-keeper, whose store caught fire one night, and by desperate exertions (personal) he succeeded in quelling the conflagration. Next day he felt his heart intermit. He consulted several medical men at home without satisfactory result, so at last came over here, when I was able to send him away rejoicing; and some eighteen months afterward he called to say how very much better he was; and certainly the heart had largely forgotten that night of effort and excitement.

A common form of intermittency is that found after indigestible meals. Here the old dogma, "irritation of the gastric fibres of the vagus," may be used to conceal our lack of more precise knowledge, or in some cases the presence of elastic gas in the stomach, acting upon the heart through the thin diaphragm, may be the cause of the disturbance. Commonly such disturbance is seen in females of a highly developed nervous system; but is by no means confined to them. It is met with in persons of firmer tone after a debauch, or a period of watching with little sleep, or any other cause which may sap the energy of the nervous system. When such disturbance is found, with evidences of asthenia in the heart, as the result of a hard spell of nursing, for instance, time must be allowed for the heart to regain its tone.

Marked slowness of the heart's action is generally a congenital or family affair; but exceeding rapidity of the heart's action is found in certain cases as a new feature in cardiac disorders. Suddenly the heart will run off at the rate of two hundred beats a minute, and keep this up for hours, the attack passing away as suddenly as it came on, leaving the patient exhausted; and no wonder, for the heart must be like a tetanized muscle with this tremendous activity. The explanation of such cases seems to me to be a rapid discharge of the centres of the accelerator fibres of the vagus in the medulla—a species of discharge allied to that of the motor centres which gives epilepsy.

Then there are cases of arrested action of the heart which may have varied causal relations. Certainly suppressed gout will produce surprising lack of energy in the heart; so much so that I have seen a robust man confined to his bed and feeling as if he would faint on attempting to rise, the whole passing away with an attack of gout, and leaving not a wrack behind to tell of it. In other cases the effect is less pronounced; yet the symptoms of heart-failure are closely simulated, causing much alarm and apprehension of fatty degeneration; such condition also passing away with an explosion of gout.

Comparatively sudden failure of the heart's action is not rarely seen in over-worked men at the present day, and is a malady of which we shall see more ere long, in my opinion. It may occur in stalwart men, and one marked case in a remarkably strong man came under my notice last summer. A yachting tour has resulted in my seeing no more of him. This failure of the heart's action may be due to distinctly different causes. Two illustrative cases will demonstrate this. A lady of admirable physique was severely ill-used by her husband, and left him. At that time she suffered from want of tone in her heart, with attacks of palpitation. Soon she got all right. But she was induced to return to him; he again ill-used her; an attack of bronchitis confined her to the house, it being winter, so she could not escape. When she did the heart was found acting feebly, and, in place of the attacks of palpitations, she was subject to syncopal attacks, in which the heart's action was very feeble, though she never actually fainted. She recovered completely from this condition. Thus there seemed to be exhaustion of the organic nervous system, as the cause. The next case contrasts with this. A medical man of magnificent physique, and great prowess as a swimmer, came into my room one day leaning on his stick. He complained of inability to exert himself, and, at times, of feeling as if he would faint when the heart's action was at once feeble and slow. The heart was sound enough. He also complained of pain betwixt his shoulders. He was rather surprised when I suggested we should step over to Dr. Fevrier's and ascertain what it was that was wrong in the spine. He decided that there was some rheumatic thickening of the spinal meninges, and advised counter-irritation. As we returned,

I explained that this was evidently the cause of his attacks—that, in my opinion, they were due to some irritation acting through the inhibitory fibres of the vagus. This was a new light to him; but the consequence has been that with the disappearance of the spinal symptoms the heart symptoms have vanished, and he is now as active and energetic as ever he was.

Such, then, is some account of a subject yet very far from clear. As to valvular affections and their recognition, probably we have little more to learn. As to changes in the muscular wall, whether gross or histological, our ideas are clearing. But about neuroses of the heart we have still a very great deal to learn. They are on the increase at the present time, like all neurosal maladies. The older men have not described them, in great measure owing to the fact that they did not see them as we are doing. In another generation they will have become so important that a general recognition of them is certain. In the meantime reflex palpitation is being clearly established, though reflex inhibition is a recent step forward. The effects of disturbance acting through the inhibitory and through the accelerator fibres of the vagus are just dawning upon us. When these maladies can be described in the noontide daylight of full knowledge, the writer of these articles will be but a memory being rapidly lost in the busy activity of a future time.

THE PREVENTION OF SUMMER COMPLAINT.

By HENRY DWIGHT CHAPIN, A.M., M.D.,

ATTENDING PHYSICIAN TO THE OUT-DOOR DEPARTMENT, BELLEVUE HOSPITAL (CHILDREN'S CLASS).

UNDER the general term "summer complaint" are comprised a number of different conditions, including simple functional diarrhœa, inflammatory diarrhœa, dysentery, and cholera infantum, as they occur during early life in the heated part of the summer. Cholera infantum is rather a rare disease, and occurs infrequently in comparison with the other affections just mentioned. The term is often loosely applied to every form of infantile diarrhœa occurring in summer, but it should only be used when true choleraic discharges are present. The heavy mortality of the summer diarrhœa of infancy and the difficulty of controlling it, suggests the inquiry whether more cannot be done in the line of prevention. The causes are well known, but do we insist with sufficient stress upon their palliation or removal? One of the most frequent, and to a great extent preventable causes, is improper feeding. The carelessness and indiscriminateness of the diet allowed to young children is a matter of continual surprise. Frequently mere babies are allowed to sit at the table and partake of the same food as adults. I have recently attended a baby, nineteen months old, who experienced some inconvenience after eating huckleberry pie with the rest of the family; and in another case a mother had given her baby, aged fifteen months, a little corned beef hash. Although an unwholesome diet may sometimes be apparently taken with impunity, there still follows an impairment of the digestive power of the stomach and intestines that is a continual predisposing cause of diarrhœa. Nor is it easy to understand how this could be otherwise. The undigestible contents of the stomach and intestines speedily undergo fermentative changes that eventuate in the formation of butyric and fatty acids. These irritating acids frequently stimulate the intestinal follicles to excessive secretion and increase the peristaltic movements. The marked acid odor of the vomited matters and fecal discharges, and the accompanying excoriation of the buttocks, are frequently evidences of this fermentative process. Too early weaning of infants, especially just before, or during the hot months, is a fruitful source of trouble, and should always be avoided.

In order to show the dangers of summer diarrhœa to artificially-fed babies, the Bureau d'Hygiène of the city of Rheims, France, in July, 1882, made a slight change in the form of death-report required in cases of infantile diarrhœa. Children dying from this disease were divided into two classes—those nourished by mother's milk, and those brought up by hand. From July 1st to December 31st, thirty-one infants nourished at the breast and two hundred and seventy-two brought up on the bottle died of infantile diarrhœa. While these figures show a larger relative mortality in hand-fed babies than we are accustomed to see here, they nevertheless enforce an important fact. And yet babies are often removed from the breast at this season for the most trifling reasons. Even serious objections to nursing must be carefully considered before taking the risks of an exclusively artificial diet in hot weather. Despite menstruation, and even of pregnancy, it is often better for the infant to continue nursing until the weather becomes cooler. The thirst naturally produced by the heat causes the baby to wish to nurse or take the bottle very frequently, and as a result colic and indigestion are soon induced, which often eventuate in diarrhœa. The cause of this is evident. There is a continual rapid evaporation from the skin, and as a result of this fluid loss the watery parts of the food are quickly absorbed to make up the deficiency, leaving the thickened solid part to ferment and cause irritation. This cause of diarrhœa can be removed by giving milk or other nourishment only at suitable intervals, but allowing the baby to drink frequently of water, administered in small quantities at a time. The avidity with which it drinks will confirm the indication for its administration. Thin barley-water often agrees better with the stomach in hot weather, except in very young babies. Restricted nursing and a more liberal supply of water would prevent many attacks of diarrhœa in infancy.

It will be impossible to cite all the common errors in infantile diet that help to form such a heavy mortality during the summer months. Every physician can do much in individual cases to lessen this mortality by finding out and preventing these errors. I think that mothers, especially those living in tenement-houses, should receive minute and explicit directions as to the diet of their babies at different ages, and any society that will attempt such a work can do vastly more good than in trying to teach ladies how to support a mangled limb until the doctor arrives.

The intense and all-pervading heat of the summer months forms a factor in infantile diarrhœa that is not so easy to eliminate. And yet much can be done even here in the way of prevention. Heat acts directly and indirectly in causing the mortality due to summer diarrhœa. It acts directly on young children by depressing and rendering more susceptible their nervous energy, by enfeebling the digestive organs, and by increasing but weakening the action of the heart. The indirect effects of heat are caused by fermentative changes in the food of infants and in surrounding domestic and civic filth. The direct connection between decaying refuse matter and summer complaint is shown by the fact that wherever the filth is greatest the death-rate from this cause is highest. There is a plain indication here for preventive treatment. The physician must insist upon the most scrupulous personal and domiciliary cleanliness during the hot months, while boards of health look after the condition of sewers, streets, and drains. Fermentation changes in milk can be largely obviated by boiling it when fresh to destroy all germs, and then adding a little alkali.

The direct effect of heat, aside from any increased foulness of the air that it induces, is an interesting point to consider. I have prepared the following table from statistics derived from the Board of Health. It consists of a comparison of the death-rates from diarrhœal diseases between two winter months and two summer months, together with the mean temperature of each month. Under diarrhœal diseases are included simple diarrhœa, dysentery, entero-colitis, cholera infan-

tum, cholera morbus, Asiatic cholera, diarrhœal gastro-enteritis, and diarrhœal enteritis.

Deaths from Diarrhœal Diseases in New York.

	Jan.	Feb.	July.	August.
1882.				
Mean temp., Fahr.	28.77°	35.21	75.79°	73.42°
Deaths under five years	34	32	1,533	817
Deaths over five years	14	15	131	149
1883.				
Mean temp., Fahr.	25.18°	30.24	74.46°	70.40°
Deaths under five years	32	32	1,355	507
Deaths over five years	14	16	125	116

A glance at this table will show the tremendous increase in the death-rate under the age of five years in comparison with that occurring above that age, the difference in winter being about double, while in summer it is vastly higher than that proportion. It also shows that the month having the highest mean temperature, July, has much the highest death-rate in children under five years, while in cases above five years of age there is no appreciable difference between July and August. In 1882 and 1883 there was an increase of the mean temperature of July over August of from 2.37° to 4.06° Fahr. The difference in heat represented by these few degrees doubled the death-rate in children under five years. As tenement-houses and streets are no cleaner in August than in July, and as there is quite sufficient heat and moisture during August to cause free fermentation in any filth, it is evident that the increased infantile mortality during July is due to a slight increase in the heat, as the other elements causing it are about the same. It is an impressive commentary on the inability of infants to stand a high temperature well, that in 1882 an increase of 2° in temperature was sufficient to raise the death-rate by just 716 young children in one month. It is also seen by referring to the table that the mean temperature of July, 1882, was 1.33° higher than that of July, 1883, and there were 178 more deaths in children under five years in the former month. One explanation of the much higher death-rate of July over August may be that most of the weak, bottle-fed babies die during the first heated period; but this can be offset by the fact that infants a little stronger and having more resisting power finally succumb in August, exhausted by the long-continued heat. I think that sufficient stress has not been devoted to the injurious effects of heat itself upon young children by writers on this subject, and that relatively too preponderating an influence has been given to impure air. The disastrous effects are due to such an intimate combination of these two agents that it is somewhat difficult to estimate their separate influences. But while it is easy to understand the injurious effects of breathing a foul atmosphere, and its depreciating consequences are constantly seen, yet the system, in a sense, gets accustomed to impurity, and throws it off more or less readily. Young children live for months shut up in filthy apartments without dying, and even seeming to enjoy tolerable health.

Of course they grow scrofulous and readily fall victims to disease; but, after all, the organism seems to establish a sort of toleration for filth, just as for arsenic and many other poisons. Continuous and intense heat does not seem to allow of any such escape. It is difficult to explain exactly the reason that excessive heat produces such fatal results in early life. It has been affirmed that, in accordance with the physiological law of vicarious functional action, the over-stimulation of great heat interferes with the secretive powers of the skin, and hence the mucous membrane is excited to a morbid activity. If such a relation exists, it is probably more intimate in children than in adults. Again, the depressing effect of great heat upon the nervous system is familiar to every one. In infants, as the vegetative processes are most active, the great sympathetic ganglia presiding over them hold a very prominent position in their nervous economy, and are hence markedly affected by depressing agents, as heat. Impaired innervation of the stomach and intestines follows, which results in a diarrhœa upon the slightest irritation. Physiological processes, under the especial control of the sympathetic nerves, require a longer time to be influenced by perturbing causes than those controlled by the cerebro-spinal system. According to Dalton, inflammation of any internal organ is rarely established until twelve or twenty-four hours after the exciting cause. The increased mortality in young children does not usually commence until a day or so after the great heat begins, and continues a like period after the cessation of the heated term. While there may be some uncertainty as to the exact way in which heat acts, its unmistakable effects lead us to ask whether even here some preventive measures may not be of avail. The free use of the bath, which is apt to be too much neglected, especially among the poorer classes, will do much to obviate the depressing effects of excessive heat.

In an exhaustive monograph; "On the Effects of High Temperature upon the Public Health," Professor Stephen Smith has thoroughly discussed the subject of warm and cold bathing in this connection. The cold bath is generally used for cooling the body; as it quickly abstracts heat from the surface by conduction, there follows a sudden reduction of the temperature. By constringing the vessels of the skin, however, the blood is forced to the internal organs, which are thereby stimulated to functional activity, and hence as a secondary effect heat is produced. At the same time the mass of blood, by leaving the surface, ceases to remain in contact with the cool medium. After this temporary rise, the temperature soon falls to normal, and equilibrium is restored. The effect of a cold bath upon the body temperature would be thus represented by a curve indicating first a fall, next a rise above normal, and finally a return to the average. When a warm bath is used heat is communicated to the body by conduction, and the temperature is elevated. At the same time, by relaxation of the blood-vessels and skin, the cutaneous secretions are increased, the blood is withdrawn from the viscera, and a cooling process takes place by means of active evaporation. In a warm bath, therefore, the curve first rises, but next falls below normal, and finally reaches the average. An increased coolness follows its administration, while a warm sensation often follows a cold bath on a very hot day. Wunderlich states that in tropical countries, and very hot seasons, no means of cooling is so lasting as a bath or douche of very warm water. The bad effects of great heat upon young children can, then, to a certain extent, be obviated by giving them a suitable bath every afternoon. If the children are old enough, place them in a tepid or warm bath, and let them play there for an hour. The skin will thus be kept active, the blood cooled by being brought to the surface, and evaporation continue for some time. Of course the water should not be used so warm as to produce relaxation. In the case of babies too young for the bath, frequent spongings of the whole body with lukewarm water will fulfil the same indication. A little vinegar or alcohol may be added to the water to aid evaporation. If an infant begins to droop, it is well to give whiskey or brandy, in doses of from two to three drops for every month of its age up to a year, and repeated several times a day. Finally, infants should be taken daily, in the early morning or evening, to parks, or on a ferry-boat, where they can get pure air. If well babies could be thus daily refreshed they would be much less likely to fall victims to summer complaint. In the tenement-house districts of this city they are often confined to the house for days. The slightest manifestation of diarrhœa in children during the hot months should be speedily arrested. Many mothers have an idea that a diarrhœa occurring during teething should not be quickly checked. Very frequently babies

are brought during these hot days to my clinic at Bellevue half dead, or dying, from summer diarrhœa that has been allowed to run on a week unchecked, because it occurred during dentition. Many deaths occur annually from this mischievous notion on the part of mothers.

Just now, as we are beginning to hear much of cholera, adults will also be warned against allowing a diarrhœa to continue unchecked. It is peculiar to notice in this connection that while summer diarrhœa attacks by preference young children, Asiatic cholera, to which it bears some resemblance in many of its symptoms and pathological changes, does not attack, as a rule, the period of childhood.

A CONTRIBUTION TO THE LITERATURE OF PLACENTA PRÆVIA, WITH A HISTORY OF EIGHT CASES.

By E. P. CHRISTIAN, A.M., M.D.,
WYANDOTTE, WIS.

The comparative rarity of this accident of parturition with others of the dangerous complications, and the dismal records of its literature, are reasons sufficient for any physician having had any considerable recorded experience with such cases for giving their histories and results to the profession. Even though the results of one's experience may not differ from the average, and he may have no new suggestions to offer as regards their management, yet the recorded histories of their individual peculiarities, indications, and results serve to increase the rather meagre statistics on which, as yet, theories and conclusions are based, and will help to the increase of that larger mass of facts upon which more reliable conclusions may be built in the future. Fortunate for the parturients is it that the danger of exposure to this accident is so small, but unfortunate for obstetric science that its comparative rarity affords any one individual so limited experience from which to generalize. This infrequency, I suppose, arises not merely from its being an unnatural condition, the sequence of conception occurring in an abnormal state or condition of the uterus, or from accidental violence to the mother disturbing the ovum in its earliest period of intra-uterine existence. If this were all, we might expect the accident of placenta prævia to be of even much more frequent occurrence than it is. But I suppose it to be in that wonderful provision against the future danger to the mother, of childbirth at term, in the fact of the natural tendency of this condition to terminate in an early abortion. This condition I believe to be the cause of very many early abortions, often sufficient of itself, oftener perhaps requiring only the slightest accidental violence superadded to induce the abortive process, and which latter accident invariably is alleged as the cause. That the condition of placenta prævia has existed in numerous early abortions of which I have had the care, I have certain and indubitable proof from observation; and when the patient, either by sufferance of nature or the aid of medical art, has advanced to later stages of pregnancy, the tendency to miscarriage still continues, as is evidenced by the prematurity of so many labors after the stage of viability of the child has been reached; and when the tendency to early abortion has been surmounted, the woman has escaped that accident only to become exposed to increasing dangers at parturition in proportion to the stage of advancement toward full term. And as this condition—placenta prævia—is a frequent cause of abortion, so is the reverse equally true, that frequent abortions are a cause of placenta prævia, or of the condition of the uterus which predisposes to the accident. I suppose there is no more frequent cause of a subinvoluted and enlarged and patulous uterus than frequent abortions. Such an uterus, with its unopposed walls, fails to retain the ovum at its fundus on its arrival and entrance from the Fallopian tubes, and it falls by gravity or is washed down by menstrual secretions, or is displaced by slight jars or other violence, and reaches the lower portion of the uterus, there to form its attachment.

I have stated that the literature of placenta prævia presents but dismal records, which fact is sufficiently well understood by the profession in a general way, but only realized in its full significance by one's individual experience. During the past year there have been a number of contributions to the literature of the subject in the medical journals, and which exhibit better results, as far at least as fatality to the mother is concerned, than we can be justified in drawing from the statistics of text-book authorities. Perhaps this may be in some measure because the more favorable exhibits are the most likely to reach the light of publication. I shall make reference to such of this recent literature as has come under my notice, both for the statistical results, for comparison's sake, and also by reference to some of the conclusions.

As to the general average of fatality in placenta prævia, Churchill states (edition of 1860): "In placenta prævia, under ordinary management, one in three, or thereabouts, of the mothers are lost, and more than half of the children." This statement has been criticised as exaggerated. If it represents that of all cases occurring, the unpublished as well as the published, it is probably not an exaggerated statement. In fact, as to the fatality to children it probably does not represent that sufficiently high even under skilful management.

T. Curtis Smith, M.D., of Aurora, Ind., in a paper published in *The Medical and Surgical Reporter* of Philadelphia, July 14, 1883, states that Dr. E. W. King, of New Albany, Ind., has gathered two hundred and fifty cases occurring in the practice of physicians of that State. "Of that number there was a loss of fifty-five mothers, or twenty-two and one-half per cent. The mortality among children was one hundred and thirty-five, or over fifty-seven per cent." These figures would give a loss of mothers of 1 in 4.4. "Of three hundred and thirty-two cases collected by Schwartz, there was one death in 3.86." "Simpson states a mortality of 1 in 3.6." "Trask (Prize Essay) 1 in 3.95." Dr. Smith, author of the paper, gives a history of three cases in his practice, one of which was of central implantation—delivery by version. All the mothers were saved, and two of the children. Dr. Smith remarks: "It is an unhappy fact that a larger proportion of cases of placenta prævia give mal-presentations than where the placenta is otherwise normally attached, and hence version is often a necessary procedure and often causes a fatal issue."

In Dr. Simpson's tables a large number, twenty-three in ninety-one, or about twenty-five per cent., were of mal-presentations, as of shoulder, arm or hand, and head. This fact, besides its bearing on the rate of fatality, has another interest to us in its bearing, or the hint it gives us of the causes of this accident—placenta prævia—to which we have made reference, and shall do so again further on.

D. C. Davis, M.D., of Columbus, Wis., read a paper on this subject before the Wisconsin State Medical Society, and published in the "Journal of the American Medical Association, September 15, 1883," in which he records the exceptional experience of having met with seventeen cases of placenta prævia in sixteen years of practice. He had saved all the mothers, and saved but one child. He gives a brief history of two cases in succession of centrally implanted placenta terminated by perforation and turning, and formulates the following conclusion, emphasized in italics: "*That without doubt rapid perforation, version, and delivery offers the easiest, speediest, and safest chance of life to the child and safety to the mother of any manner or mode of management heretofore advocated and known to me.*"

He also makes the following statement of a fact remarked also by others, and so markedly corroborated by my own experience, and a truth of such import and relevancy, that I consider it worthy of special emphasis:

"Another fact in favor of this mode of procedure is the dilatability of the os and cervix in cases of placenta prævia hemorrhage, for I know whereof I speak when I aver that the uterus, from loss of blood in these cases, is rendered more passive and dilatable, and consequently version is more easy of accomplishment than in any other mal-presentation."

Dr. J. K. Bartlett, Chairman of Section of Obstetrics and Diseases of Women, in his report at the meeting of the American Medical Association in 1883, has the following on this subject: "The report of Mr. Hoffman, of Berlin, on this subject deserves notice from its unusually favorable results. He cites forty-six cases. Of these, three were so near death when seen that there was no opportunity for treatment. Of the remaining forty-three, six were treated by the waiting method and the tampon. In the other thirty-seven no tampon was used. Of the six treated by tampon at an earlier date, one died, two had a long and severe illness, and four children were dead. Of the thirty-seven treated differently one mother only died, and she had been treated by tampon for twenty-four hours, and the placenta was offensive when delivered." (No statement of results to children.)

With this cursory review of some of the recent literature of placenta prævia as an introduction, I will now give briefly the histories of my own cases, eight in all.

Case I.—Mrs. C——, American; seventh labor. Patient weakly and delicate, but obliged to do her own housework. The subject of several abortions. No complications in previous labors at term. Commenced flowing at about seven and one-half months; controlled each time by tampon. Labor was ushered in and accompanied by fearful and exhaustive flooding. Placenta implanted centrally over the os, and was expelled in advance of the child's head, which was immediately after delivered by forceps. The child presented evidences of having been dead for probably some days previous, by reason of commencing decomposition. Woman had a very slow and tedious recovery. This, my first case, and at a very early period of my practice, was the worst case I have ever had. With my present knowledge and experience, in a similar case, I should perforate, turn, and deliver. This, as was shown after delivery, would have made no difference as far as the child was concerned, but would have terminated the labor more rapidly and have saved the woman considerable blood.

Case II.—Mrs. S——, English; ninth labor. Heavy flowing came on at 2 P.M.; easily controlled, and labor pains set in at 8 P.M. Examination showed marginal attachment of placenta, and head already descended so as to check the hemorrhage. The child was speedily born, the placenta coming away immediately after. No interference was necessary to hasten labor, and the woman quickly recovered. The child was dead.

Case III.—Mrs. H——, Irish; first labor. Flowing at frequent intervals for past month. Had pains since morning, with hemorrhage. I saw her for first time at 9 P.M., when she was flooding. Found marginal attachment of placenta. Os only dilated to admit two fingers, but soft and easily dilatable, notwithstanding this was a primipara. There had been great losses of blood, and of course great prostration and relaxation. I dilated rapidly with my hand, turned readily, and delivered speedily. Child dead and decomposing. Mother had felt no life for five days previous. Mother recovered quickly.

Case IV.—Canadian French; sixth labor. I was called to the patient on account of dangerous flooding. Examination showed the os already well dilated, with head presenting, and marginal attachment of placenta; pains feeble and inert, as usual after excessive loss of blood, and insufficient to press the head down with sufficient force to check the hemorrhage. I applied the forceps, bringing down the head, which immediately checked the flow, and readily and easily delivered a large and living boy. A slight incident in this case illustrates how, without great carefulness in the application of the blades in such cases, a serious accident might occur, and one in regard to which I do not recollect to have seen any caution, perhaps because writers usually advise against the use of the forceps in placenta prævia. Having applied the blades, I commenced with a gentle traction, upon which the woman screamed out that I was tearing her. I unlocked the blades and carefully reapplied, with no further complaint on traction. I had doubtless grasped a part of the membrane of the placenta between the blade and head. The woman made a speedy recovery.

Case V.—Mrs. G. B——, Canadian French; tenth labor. I was called to this patient some distance in the country, on account of dangerous flooding, the woman being in eighth month of pregnancy and not yet expecting labor. Examination showed os uteri soft and dilatable, but as yet dilated only to admit finger, and central implantation of placenta; very feeble pains, as usual after excessive hemorrhage, and woman dangerously prostrated for so unadvanced a stage of the labor. I commenced giving ergot to promote contraction, assisted with digital dilatation, and, as soon as practicable, separation of placental attachment on one side until the bag of waters could be felt, which was ruptured. This, with the increasing ergotic contractions, brought the head against the bleeding surface, checking the hemorrhage. Labor progressed favorably, and the child was born, the placenta having become totally detached by the advancing head, and coming before it. The child was dead.

Case VI.—Mrs. J——, Canadian; seventh labor. Threatened abortion at fourth month, with hemorrhage; again at fifth month in increased quantity; recurring attacks in increasing frequency up to the seventh month, when indications of labor set in with such terrific losses of blood that on my arrival I considered it necessary to terminate labor as speedily as possible to save the woman's life. The safety of the child, under the circumstances, was considered a small matter, especially as the woman was only at the seventh month, and I considered that the previous long-continued hemorrhages had in all probability compromised its chances of life. At any rate, it was necessary that assistance should be given promptly to the mother or she would be lost. Examination showed central implantation; os dilated to some extent; easily dilatable and soft; pains inert. Gave ergot liberally; accomplished rapid manual dilatation; detached placenta; performed version, and delivered a dead boy. Woman recovered, but required time to recuperate from her excessive prostration.

Case VII.—Mrs. C. S——, German; fifth labor. Posterior marginal implantation of placenta, with presentation of left arm and prolapsed funis; patient attended by a midwife, who sent for me on account of the mal-presentation and severe hemorrhage since commencement of labor, which was at full term. Os sufficiently dilated on my arrival for immediate assistance, which I proceeded to render by turning the child and delivering by the feet, and which was readily accomplished, and the woman delivered of a dead boy. Woman speedily recovered.

Case VIII.—Mrs. G——, German; mother of two healthy children, born at full term, by first husband, and of numerous abortions by her second. The case was one of miscarriage at sixth month, and unaccompanied or preceded by hemorrhage until after perforation of placenta, and then comparatively insignificant. The case was peculiar and unique. Threatened abortion, as usual, at about the third month, with discharge of water, but without hemorrhage. Water had continued dribbling away ever since. Labor came on and progressed very slowly on account of inefficiency of pains. The os having after many hours become well dilated, I concluded to rupture what, from the undeveloped condition of placenta at that stage of gestation, from its being free from attachment in the neighborhood of the os and yielding

before the pressure of the finger, and from the absence of hemorrhage, I did not suspect to be the placenta, but the amniotic bag, for the purpose of engaging the fœtus in the mouth of uterus, and increasing the force of the inert pains. I found this unusually thick, and more difficult of penetration than usual, and its accomplishment was followed by a discharge of blood for the first time. A leg was found presenting and brought down, and the body engaging the hemorrhage ceased and child was soon born. It was felt to move during extraction, but showed no indications of life after it was born, probably owing to some delay with the head. Attention was now given to extraction of the placenta, which was found covering the os and firmly attached away from its margins. So firmly adherent was it, and so sensitive the os, and so painful were manipulations, that it was necessary to put the patient under chloroform for that purpose. Examination of the placenta showed the rent near one border, through which the child had been extracted. The separation of the placenta, in this case, I suppose to have been going on gradually since the rupture of the amniotic sac in the third month, and accompanied by inflammatory changes in the parts, such as to close the mouths of exposed vessels and prevent hemorrhage. Dr. Simpson has given as one of his therapeutical deductions in regard to the physiology and treatment of placenta prævia, "that inflammation of the uterine structures, particularly of the cervix, is especially likely to supervene when delivery is attended by placental presentation." This was a complication of my first case also, notwithstanding numerous exhausting hemorrhages, and which retarded her recovery. In that case it may have been in part due to, or aggravated by, the use of the tampon.

These are all the cases of placenta prævia it has been my good, or bad, fortune to meet in a practice extending over thirty-two years. I have met with three cases in one year, and then again have passed a period of ten years without meeting a case.

Analysis of the cases shows four of them central or completely covering the os—Cases I., V., VI., and VIII.; and four marginal—Cases II., III., IV., and VII.

Two cases were delivered by forceps, one of central implantation, in which case the child showed evidences of having been dead for days before labor set in; the other, a case of marginal implantation, the child was born alive and healthy, the os being sufficiently dilated to admit of easy application of forceps on my arrival. This was the only living child of the whole eight cases. Three cases were delivered by version; one of central, in which the placenta was detached for that purpose, and two of marginal: one of the latter was complicated by descent of funis and an arm. One case by perforation of placenta and delivery by presenting feet. One case by manual dilatation and ergot only, and one requiring absolutely no interference, a speedy and easy delivery, and yet the child was born dead. In all the cases of version or manual dilatation, the os was found soft and easily dilatable, in accordance with the observation of Dr. Davis, "that the uterus, from loss of blood in these cases, is rendered more passive and dilatable, and consequently version is more easily accomplished than in any other mal-presentation." All the mothers were saved, and but one child. But how little bearing the management of the cases during labor has had on the rate of mortality to the infants will be shown by a consideration of the circumstances of their histories. Two of the children showed evidences of having been dead for days previous to labor—destroyed by the previous hemorrhages, by asphyxia, as Cazeaux states, from interference with the placental circulation. One was a case complicated with other mal-presentations, rendering version necessary, and in such cases alone the mortality is very great, and when superadded to placenta prævia leaves but a hopeless chance for the safety of the child. One was a case of premature delivery at six months, in which the child would have been in any case lost, because of its immaturity. This would leave but four cases, or fifty per cent., in which the accidents or management of labor could be at all supposed to have affected the rate of mortality to the infants. But in addition, Case II. was an easy and speedy labor, with absolutely no call for interference, and yet here the infant was born dead, destroyed, doubtless, by the preceding hemorrhage, only a few hours before; and again two more of the cases (V. and VI.) were premature deliveries at eight and seven months, in which cases, if not destroyed by the hemorrhages, the chances of life to the children were correspondingly lessened by their prematurity. In Cases I. and V., the placenta came in advance of the child, which would seem to be a circumstance almost certainly fatal to the infant, and very dangerous to the mother. Churchill remarks in regard to such cases, "the mother is not always lost in these cases;" and again, "now it appears that these instances are not so rare as was supposed." He states that Dr. Simpson has collected one hundred and thirty cases in which the placenta was either expelled or extracted first, and that in all ten women died, or one in thirteen—and of one hundred and ten cases the infant was born dead in seventy-three, or sixty-nine per cent., and saved in thirty-three, or thirty-one per cent. Acting on the now generally recommended and accepted method of perforation of placenta and version, this accident will be less likely to occur, and yet we venture to say that this operation will not always prevent the extrusion of the placenta in advance of the child. I have had more than once separation of a normally attached placenta in the operation of turning for abnormal presentations, and have lost the child probably in consequence. It will be no less likely to occur when attached about the os.

The one only child saved of my eight cases was delivered by the generally disapproved method of the forceps. No doubt the timely and opportune application was proper and correct in this case. The summary of results from the cases given in the papers to which I have made reference is as follows:

	Number of cases.	Mothers saved.	Per cent.	Children saved.	Per cent.
T. C. Smith	3	3	100	2	67
D. C. Davis	17	17	100	1	6
Hoffman	46	41	89	—	—
My own	8	8	100	1	12.5
	74	69	97.25	4	14

These results, so far as any conclusions may be legitimately drawn from such meagre records, show much more favorably for the mother, and contrariwise for the infant, than the results commonly given by writers; and that while there seem to be good reasons for believing there has been an improvement in the chances for the mother, that no such encouragement is warranted as regards the child; nor from a consideration of the nature and circumstances of the accident does it seem probable that any great improvement in that respect can be attained for the following reasons:

1. If my cases are a fair average exhibit, from twenty-five to thirty-three per cent. of all will be destroyed by disturbances of the circulation previous to labor.

2. From Simpson's statistics twenty-five per cent. of all cases will be complicated with other mal-presentations, compromising the life of the child in a very large proportion of them.

3. From twenty-five to thirty-five per cent. of all will be premature births. If, then, to these circumstances we add the risks from hemorrhage in labor, besides the risks from version and other artificial interference and aids, we can understand that the risks to the child must always remain so great as to permit of the safe delivery of but a small proportion, and we may also understand why

nature, in her beneficence, looking to the safety of the mother in the great majority of the cases, probably prefers the sacrifice of the offspring by an early abortion.

In conclusion, what are the causes of this accident of parturition which, despite of all proposed methods of management, continues, in its fatality to children, as merciless as the execution of the Herodian edict for the slaughter of the innocents, and, more merciless than that, destroys also a large percentage of the mothers, causing lamentation and mourning in households, and anxious care and harassing disappointment, and vexatious dissatisfaction to the physician with the results of his most energetic and conscientious efforts to bring the labor to a safe and happy termination, not only as regards the mother but to save her offspring? The condition is unphysiological, and I should suppose peculiar in and possible only to the human female, unless, perhaps, the quadrumana may be exposed to it. Writers have particularly called attention to the fact of the frequent complication of this accident with other coincident mal-presentations.

Dr. Simpson, as we have stated, gives a table of twenty-three cases of other mal-presentations in a table of ninety-one cases of placenta prævia. Dr. T. Gaillard Thomas, in a clinical lecture on "Causes and Treatment of Abortion," published in the *New York Medical Journal*, January 24, 1884, states that "there are two great causes of abortion—first, a posterior displacement of the uterus, which interferes with a proper development of the organ; second, syphilis." But the first is the only one which has any relevancy to our subject, and this because it is evidence from eminent authority of that condition as the most frequent cause of abortion which we regard as the most prolific cause of mal-positions and placenta prævia, not posterior displacement of itself, but the cause of posterior and of other displacements. For what is the cause of these displacements?

The cause is in the increased bulk and weight of the uterus from subinvolution, as is also that of unnatural relaxation and patency. In a paper before this Society, two years ago, on some mal-presentations, I I stated this as the prolific cause of mal-presentations, placenta prævia, and abortions. These accidents—mal-presentations and placenta prævia—occur for the most part in multiparæ or in multipregnant women, and frequent conceptions, but more especially repeated abortions, are the most prolific cause of unnatural relaxation and patency, and are, again, the cause of too frequent conceptions. A relaxed uterus with an enlarged and patulous cavity fails to arrest and detain the ovum on its arrival in the uterus from the Fallopian tubes, or it is washed down by the menstrual secretions, or is more readily displaced by the movements of the mother, or by any violence or shock, and is thereby caused to form an unnatural attachment, and the same conditions may favor unnatural positions in the developing and growing germ from the very commencement of intra-uterine existence.

An Old Mode of Detecting Rabies.—To enable a person who had been bitten by a dog to ascertain whether or not the animal was rabid, the *Universal Magazine*, a London monthly publication, in its issue of November, 1753, published the following, which is accredited to "The Memoirs of the Royal Academy of Sciences at Paris:" "When a person hath been bitten by a dog that is apprehended to be mad, it commonly happens that the dog is killed before one is assured of his condition, and the person bitten continues in a cruel uncertainty. Mr. Petit, the surgeon, hath an expedient for putting an end to this uneasiness. He rubs the throat, the teeth, and the gums of the dead dog with a piece of meat that hath been dressed, taking care that there be no blood to stain it, and then offers it to a living dog. If he refuses it with crying and howling, the dead dog was certainly mad; but if the victuals have been well received and eaten, there is nothing to fear."

ON THE UNTRUSTWORTHINESS OF FLUID EXTRACTS,

With Practical Notes Regarding Rhus Toxicodendron, Pulsatilla, Cereus Bonplandi, and other Plants.

By N. L. NORTH, M.D.,

Brooklyn, N. Y.

"Untrustworthy" ought to be written after the name of many of the fluid extracts of medicinal plants as usually found on our apothecaries' shelves. I have a habit of tasting, at a subsequent visit, of nearly all the medicines I prescribe, and I find there is a large number of the fluid extracts in many of the officinal and unofficinal[1] forms prepared for our use by the pharmacists which taste exactly alike. That taste is a peculiar, stale, dirty, gritty one, often entirely wanting in the special aroma peculiar to each plant in the green state; and just here, I make no doubt, is the secret of the untrustworthiness of many of these "medicines." Instead of the fluid extract being made from the recent or fresh green herb, it is too often made from a dried, more or less inert plant, from which the volatile, and often the active principle has, perhaps, wholly evaporated.

This fact will no doubt go far to explain the sentence, "The medical virtues of this plant are too uncertain to inspire any confidence in it," or something meaning the same thing, so often found in the dispensatories. To particularize: The article rhus toxicodendron, which is dismissed by the National Dispensatory with the remark quoted above, after being thought worthy to be considered officinal under the head of Toxicodendron, is, there can be no doubt, a plant of definite and considerable power medicinally, if rightly prepared and properly used. Dr. Thomas Gifford, of Laurel, Ind., speaks very highly of its curative action in sciatica, having used it successfully for many years, even in cases of one, two, and three years' standing. Dufresnoy called attention to the rhus toxicodendron as a remedy in herpetic and eczematous diseases as early as 1798. Phillips, in his work on "The Materia Medica, etc., of the Vegetable Kingdom," refers to the rhus as a very powerful therapeutic agent in "various subacute and chronic rheumatic affections of the fibrous tissues generally." Dr. H. G. Piffard, of New York, in an editorial note in Dr. Phillips' book, confirms its usefulness. Speaking of the probable error sometimes made by physicians, mistaking the "worse-at-night" rheumatism for syphilitic rheumatism, Dr. Piffard says: "In a number of these cases we have obtained most decided and prompt relief from rhus." The whole matter turns upon the mode of preparation. The officinal fluid extract, of which it is advised to give from one to ten drops, is probably good for nothing. Dr. Gifford makes a strong tincture (one part to two of alcohol) from the green herb, gathered the last of May or the first of June, previous to the flowering of the plant. It is gathered after sundown of a lowery day. He likely in this way preserves the toxicodendric acid. Of this tincture he gives from one-tenth to one-fifth of a minim in a spoonful of water twice a day, and in some cases he advises even smaller doses. Dr. Phillips advises a tincture made by macerating one part of fresh leaves in two parts of alcohol; of this he advises a small fraction of a minim in rheumatic and cutaneous affections. The tincture of the German Pharmacopœia is made from five parts of the fresh leaves to six parts of alcohol.

Again, in the National Dispensatory we find after the description of pulsatilla, lately made officinal, "No sufficient grounds exist for its use in therapeutics." Nevertheless pulsatilla is often spoken of in the journals and

[1] I mention in this connection the so-called *unofficinal* medicinal preparations because it is a well-known fact that there are a large number of what the makers of our pharmacopœias fail to recognize as *officinal*, for decade after decade, which are, nevertheless, "in the shops," and constantly being used by very many practitioners.

in other ways by such men as Sturgis, Piffard, and Fox, of New York, and Borchiem, of Atlanta, Ga., as a remedy of much value in glandular inflammations and particularly in epididymitis. Phillips ("Vegetable Materia Medica"), after advising its use in several inflammatory conditions, says, "The fluid extract is unreliable," and recommends a tincture made of equal parts of the expressed juice and alcohol, of which he gives from one-tenth to five minims.

There is another article or herb product which I have been in the habit of using and recommending for some eight to ten years, more especially for cardiac insufficiency, that I fear may soon be hard to obtain in its proper form, as I learn that one, at least, of the drug manufacturers is already preparing and recommending a fluid extract of it. I refer to the cereus bonplandi. It is not mentioned in any of the regular works on Materia Medica to which I have access. I first saw it spoken of in the *Medical Brief* by a Dr. Goss, who, I think, is an "eclectic." The preparation he recommended and the one I have always used, when I could get it, is a strong tincture of the green herb, prepared by a German druggist, R. E. Kunze, 606 Third Avenue, New York. The tincture should have a decidedly green tint. There is a preparation of a less decided tint, probably made from a partially dried herb, which is occasionally used, but is scarcely reliable. The homœopathists have a brown preparation of the cereus grandiflora (night-blooming cereus) that I find sometimes substituted, but which has almost no value in my hands. The green tincture of Dr. Kunze is one of the most satisfactory remedies I use. In ten-drop doses, three or four times a day, it will correct "palpitation" and irregular action of the heart from functional derangement with so much certainty to the physician and comfort to the patient, as to be a source of profound satisfaction. It seems to give tone to the nerves and centres controlling the heart's movements. Even in organic disease of the heart, with valvular insufficiency, whether resulting from rheumatic endocarditis or otherwise, this remedy, through its steadying power, particularly in young subjects, gives positive relief, and in some cases appears to exert a curative action.

There are many other plants and plant products of more or less acknowledged usefulness which are gradually falling into disuse because, possibly, of the prevalent modes of preparation. The phytolacca decandra, a succulent plant, is a powerful remedial agent in local inflammatory conditions—notably in mastitis—used internally and externally, and yet the fluid extract of the dried plant is of doubtful utility. The silphium gummiferum (rosin weed) has probably some virtue in bronchial catarrh and like affections; I saw an account from a French journal, some years ago, in which it was thought to have cured phthisis. I have used it considerably, with apparent benefit, in phthisical cases. It is used in the prairie districts of the West as a domestic remedy, and for horses with the "heaves." The plant probably has virtue, but the only form in which we can get it is the fluid extract, and that, as in the case of the others named, and of many more that might be named, promises but little. I have before me a long list of fluid extracts as prepared by one of the leading wholesale drug manufacturers of New York, of which the dose list in itself is suspicious, in that in many cases it would be impossible to follow directions without danger, if the remedies were made, as they should be, with the requisite caution and care to obtain all of curative value each individual plant, at its best, affords.

I desire to add, what is evidently apparent from what I have already written, that I make no claim to practical pharmacy. My remarks should not be received as being made in the spirit of criticism, but as an expression of desire that the evils referred to might be corrected by an effort on the part of our drug-makers and pharmacists to more thoroughly study individual drugs and plants, and so treat them as to capture that in them, whether it be one or many virtues or "active principles," as that there may be results commensurate with the necessities caused by disease, and as far as may be possible uniform results when the medicine is properly administered.

A STAPHYLOMATOUS EYEBALL ENUCLEATED FOR SYMPATHETIC IRRITATION, CALCIFIED CORNEA, ETC.

REPORTED BY DAVID WEBSTER, M.D.,
PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC, ETC.

MRS. HENRY M——, sixty-three years of age, was referred to Dr. C. R. Agnew by her family physician on March 24, 1883, for advice in regard to her eyes. She gave a history of having caught cold while suffering from an attack of the measles when she was seven years old. Both of her eyes were severely inflamed then and for some time afterward. From present appearances it is evident that she had keratitis and cyclitis. The cornea of the left eye is protuberant from softening and dilatation of the eye-wall in the ciliary region, and presents two large patches of dense, apparently cicatricial opacity. The iris, indistinctly seen, is shaky, showing a probable dislocation of the lens and a fluid vitreous, and the eye is without perception of light. The right eye has corneal opacities from old keratitis, and is highly myopic with greatly reduced vision from irregular astigmatism. Both eyes have been irritable for the last few days.

Enucleation of the left eye was advised at this visit, but was deferred by the patient for nearly a year, during which time she was troubled with recurring attacks of conjunctivitis affecting both eyes. At length she consented to enucleation, and the operation was performed by Dr. Agnew on February 28, 1884.

The eyeball, which seemed to be much elongated antero-posteriorly, was put into Muller's fluid, and was examined by Dr. T. Mitchell Prudden, who on June 13, 1884, made the following report:

"*Macroscopical examination.*—The eye was enlarged, measuring 2.7 ctm. transversely and 3.3 ctm. antero-posteriorly. On section, the *lens* is loosely attached and lies considerably behind the iris at one side of the antero-posterior axis of the globe. There is attachment of the iris to the cornea at one side. The *vitreous* is soft and partially disintegrated. Depression of the *optic papilla* 1.5 mm. deep. *Retina* on one side partially detached from the choroid.

"*Microscopical examination.*—The anterior epithelium of the cornea and the substantia propria are uneven, being in some places thinned and in others thickened. The substance of the cornea shows in the anterior layers, chiefly on one side, extensive infiltration with larger and smaller irregularly spheroidal masses and globules of *calcium carbonate* (carbonic acid given off on addition of hydrochloric acid). Cornea also irregularly infiltrated with spheroidal and variously shaped cells.

"The *iris*, which is in part atrophied and much distorted, is firmly adherent to the cornea a little to one side of the antero-posterior axis of the globe, over a small area.

"The *ciliary body* is drawn backward, flattened, distorted, and partially atrophied.

"The *lens* shows in a few places hyaline degeneration of the fibres.

"The *choroid* is normal except for moderate congestion of blood-vessels in places.

"The *retina*, in general, appears normal, except that there is slight detachment on one side, and scattered areas of œdema, particularly of the external molecular layer. There is atrophy of the retina, however, about the glaucomatous depression of the optic nerve entrance.

"*Anatomical diagnosis.*—Keratitis with calcification in anterior layers of cornea, flattening, and atrophy of ciliary body, anterior synechia, displacement of lens with commencing degeneration, moderate congestion of choroid and slight detachment of retina, glaucomatous excavation of optic disk."

ELECTROLYSIS IN STRICTURE.

By H. W. STREETER, M.D.,

ROCHESTER, N. Y.

I HAVE seen such remarkable statements, from time to time, of the effects of electrolysis in the treatment of urethral stricture, that I am constrained to give the results of my experience. I would premise by saying that I regard any contraction of the urethra smaller than the normal meatus, as tested by bulbous sounds, as a stricture; and that no case is cured as long as such contractions can be detected. For although the symptoms may be relieved for the time, they are liable to return at any time upon slight provocation. No recognized authority upon surgery or electricity with which I am acquainted, claim any such results as these writers in the journals. Otis says, in a private communication to the writer, he thinks it more likely to cause, than to cure stricture. Keyes writes that he had tested it in a series of cases in Charity Hospital and found it worthless. Particulars of these cases are found in Keyes and Van Buren on "Venereal Diseases." Rockwell, one of the authors of Beard and Rockwell's "Electricity," speaks in very guarded terms of its effects.

I determined to try it as occasion should present. I tried it in all upon seventeen patients, several of whom had heard of it, while the others were bitterly opposed to urethrotomy, and all had become dissatisfied with dilatation. With weak currents of six to eight cells, at intervals of eight to fourteen days, I produced no effect; with stronger currents, the only effect was irritation and more or less inflammation. The calibre of these strictures varied from six to sixteen, and my applications varied from six to twelve in each case. In thirteen of the cases I used currents which could be barely felt by the patients (as advised by the writers referred to), and created no irritation. With four patients, who wanted anything rather than the knife, and in whom repeated weak applications failed, I tried the stronger currents, with only bad effects. All of these cases I afterward cut with Otis' dilating urethrotome, with the result of producing immediate relief, and in most of the cases, I have reason to think, permanent cure. In no other similar affection—stricture of the œsophagus, of the rectum, or organized abnormal tissue, have any such results been claimed for electrolysis when applied in such weak and superficial method as described in the articles referred to. And I know of no reason—clinical, physiological, or therapeutical—why such results should be expected, or why the urethra should be an exception to all the other tissues of the body. Any deviation from the normal calibre of the urethra is liable to produce local and reflex symptoms, which will continue as long as the stricture remains. Recent strictures may be relieved, and some cured, by dilatation, but I do not think either reason or experience leads us to expect that many strictures can be permanently cured by dilatation, and we all know how unsatisfactory even is the *relief* given by sounds. Urethrotomy by Otis' method is based on common sense, and *should* theoretically cure stricture. It may be said of it, in the great majority of cases, that it is simple and easy of performance, safe, less painful than dilating by a full-sized sound, *i.e.*, one large enough to do any good, produces immediate relief, and if not permanent cure in every case, it is more effectual than any other method yet devised.

MEDICAL STUDENTS IN GERMANY.—The following figures show the number of medical students at the chief German universities during this term: Berlin, 924, including 20 from America, 6 from Asia, and 2 from Africa; Jena, 162; Bonn, 289; Königsberg, 267; Halle, 282; Göttingen, 189; Giessen, 126; Tübingen, 224; Strassburg, 172. The autumn cyclus of the holiday course of lectures for practising medical men will take place at Berlin from September 24th to the end of October.

A PLEA FOR THE USE OF DELICATE TESTS FOR ALBUMEN IN URINE.

By GEORGE B. FOWLER, M.D.,

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY, NEW YORK POLYCLINIC; VISITING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

WHETHER, in every instance, the presence of albumen in urine, in any proportion, is necessarily the signal for an alarming prognosis, is a question destined to receive much attention in the near future. Yet, whatever be the verdict, I am convinced that albuminuria is not a physiological condition. And, while many apparently healthy people may present this symptom in a given case, we certainly are not yet prepared to say what will be the ultimate result.

To be in perfect health implies a condition easier to comprehend than define. Many trivial indispositions connected with various organs have, from their tendency to pass off, taught us indifference. But ignorance on the part of the patient of the possible significance of his slight symptoms, and failure or inability of the physician to apply minute methods of investigation, have too often proved the source of future regret and disaster.

If we are dealing with a supposed "functional" case, and look anxiously for the gradual disappearance of the morbid chemical reaction of the urine, how much more does it not behoove us to be familiar with those delicate processes, by whose means we shall be enabled to follow the intruder across the pathological territory, and back into physiological bounds.

And, moreover, if it is ever to be established that a trace of albumen in the urine is compatible with health, it will be by a skilful use of the more delicate tests. I am, therefore, not in harmony with those who say that heat and nitric acid are sufficient; for this is equivalent to the dogmatical assertion that where these reagents fail there is no albuminuria. It is a significant fact, in this connection, that neither albumen nor any of its allied compounds are met with, under normal conditions, in any of the excretions. In fact, the loss of these substances is expressly guarded against by one of their characteristic qualities, namely, indiffusibility.

The only albuminous derivatives capable of ready transudation are peptones; yet, although these are produced in such great quantity in the stomach and intestines during digestion, their loss is prevented by the provision that they must pass through the liver before entering the general circulation. In the liver they are transformed into matters having no tendency to escape.

As regards the reagents most to be relied upon in testing for albumen in urine, I will simply say a word, for much has recently been written upon this matter.

In order to determine the comparative delicacy of some of the methods, I used the serum of ox-blood, carefully drawn from a firm clot, and mingled it in varying proportions with normal urine. Now, the composition of this serum is as follows: Water, 90 parts; proteids, 8; fats, salines, etc., 2 = 100 parts.

The proteids consist of two forms of albumen, *serum-albumen* and *paraglobulin*, in about equal proportions. As these two substances are always associated in albuminous urine, and respond to the tests to be enumerated, their distinctive qualities need not be dwelt upon, and they are together reckoned as albuminous. But the trial solutions having been made with serum and water, in order to know the proportion of *albumen* detected, we must go through with a little calculation based on the proportion of albumen present in the serum. This has been done, and the results, as given below, are for albumen calculated as dry. I speak of this because most of those who have gone over this ground leave us in the dark whether with any given method (having used serum or white of egg) the percentage detected means the percentage of serum or white of egg respectively, or the actual proportion of albumen present.

As a result of numerous and very careful trials with

heat, nitric acid, picric acid, acidulated brine, potassium, ferrocyanide and acetic acid. potassio-mercuric iodide, and other methods, I found the following to be their respective capabilities :

Heat, in neutral solution, fails with .018 of one per cent. ; in slightly acid solution, reacts with .018 of one per cent.

Acidulated brine, about same delicacy as heat.

Picric acid, if carefully applied, will detect .008 of one per cent. But being of low specific gravity it is sometimes difficult to employ the contact method with it. Its decided yellow color masks its effects and interferes with its delicacy.

Nitric acid is satisfactory with an .008 of one per cent. solution of albumen, if the contact method is employed. The greater the diameter of the test-tube, and the longer it stands perfectly still, the more marked is the ring of coagulation.

Potassium, ferrocyanide, and acetic acid.—The urine being first made decidedly acid, and then a few drops of the ferrocyanide added, feint clouds of opalescence will be seen in an .008 of one per cent. solution of albumen.

Potassio-mercuric iodide[1] gives a very manifest reaction with a .004 of one per cent. solution, and, hence, is the most delicate of all.

It should be borne in mind that both picric acid and the potassio-mercuric-iodide solution, also precipitate peptones, quinine, morphia, strychnia, and perhaps other alkaloids, and the former may throw down the urates. All of these precipitates, however, completely disappear on heating the solution, thereby enabling us easily to distinguish them from albumen.

These percentages may seem to some very small and not worth detecting; but I contend that, pathologically considered, they are by no means insignificant. Let us look at it practically. Serum contains about eight per cent. of albumen (or proteids precipitable by the foregoing means). We pass about 1,500 c.c. of urine per day, and urinate about six times. That would be about 250 c.c. for each time. Now, 1 c.c. of serum in each of these voidings, or 6 c.c. in the whole, would give us .031 of one per cent. of albumen.

So we see that, although the percentage of albumen may be down among the thousandths, an appreciable quantity of blood-serum is thereby represented. And, to my mind, the leakage of 6 c.c. of serum through the kidneys per day is abnormal, and suggests danger ahead. At any rate it is well to be able to know it, so as to keep a sharp lookout.

For those who may desire to learn more regarding the origin and development of these new tests, and who are not familiar with the precautions to be observed in their application, I append a brief bibliography :

"Urine Testing," *Lancet* (Am. ed.), May, 1883, p. 466; Pavy : "Urinary Test Pellets," *Lancet* (Am. ed.), April, 1883, p. 318; Roberts : "Acidulated Brine Test for Albumen," *Lancet*, December, 1882, p. 438; Johnson : "Picric Acid as Test for Albumen," etc., *British Medical Journal*, March 17, 1883, p. 504; Johnson : "Picric Acid as a Means of Distinguishing Albumen from Peptone," *British Medical Journal*, March 31, 1883, p. 64; Ralfe : "Picric Acid as a Urinary Test," *British Medical Journal*, April 7, 1883; Johnson : "Picric Acid as a Test for Albumen," *British Medical Journal*, May 5, 1883 : Ralfe : "Peptones in Urine," *British Medical Journal*, May 12, 1883; Oliver : "On Bedside Urinary Tests," *Lancet* (Am. ed.), April, 1883.

A SATIRICAL medical review, called *Dr. Sangrado*, is published in Madrid. It was begun on November last, and has appeared every fifth day since that time.

Progress of Medical Science.

FOOD FOR THE FEBRILE. — Dr. Zasetzky (*Vratch*) considers the questions of food and drink, air, and rest, for the febrile. He unconditionally repudiates the old doctrine of keeping the patients on a "hungry" diet, consisting of carbohydrates, and insists on the necessity of their sufficient feeding. Albuminates, fats, and carbohydrates must be represented in the food for the febrile exactly in the same proportion as in the food for the healthy. He supports this demand by the results of observations, according to which febrile patients assimilate albuminates, fats, and carbohydrates in the same degree as healthy subjects. Food must be given to the febrile in comparatively small amounts at a time ; it must be mechanically prepared for digestion and must well satisfy individual tastes and habits of the patients. The febrile must be allowed to drink freely, and to choose for drinking what they like (water, wine-and-water, tea, coffee, milk, toast-water, syrup and water, or fruit-juice in water). The temperature of the drink must vary according to the patient's state (that is, when fever is high, the drink must be cold ; otherwise the patient may drink what he likes at the ordinary temperature). As regards the temperature of the air in which the patient breathes, the author comes to the conclusion that it must oscillate between 56° and 63° F., not exceeding the latter limit. The necessity of most carefully maintaining the purity of the air in the patient's room is placed by the author on a level with the necessity of good feeding. Passing to the last, but not the least, point of his article, the author substantiates his demand for the greatest possible amount of rest for the febrile. Having pointed out the well-known data referring to the influence of muscular work on various systemic functions, the author mentions his own experiments on the healthy, tending to prove that moving about leads to an increase of from four to eighteen per cent. in the excretion of nitrogen in urine ; most probably the influence of movement on nitrogenous metamorphosis in the febrile subjects must be still more powerful.

GASTROSTOMY, ŒSOPHAGOSTOMY, AND OTHER OPERATIONS FOR THE RELIEF OF STRICTURE OF THE ŒSOPHAGUS.—The frequency of carcinomatous obstruction of the œsophagus in middle life, and of cicatricial or fibrous stricture, particularly in subjects of tender years, has led Dr. S. W. Gross to collect, in the July number of *The American Journal of the Medical Sciences*, the somewhat numerous and scattered instances of the various operations which have been practised for their relief, and study and compare their relative value and disadvantages. To fulfil this object intelligently he has considered separately carcinomatous and simple strictures. The four operations applicable to carcinomatous stricture are gastrostomy, œsophagostomy, internal œsophagotomy, and œsophagectomy, of which the first three are palliative and the last curative. From the consideration of one hundred and ninety-four cases of operative procedure, Dr. Gross finds that gastrostomy has proved to be the simplest, most rational, and safest of the four operations for the relief of carcinomatous stricture. Increasing experience demonstrates that the results are growing better and better, which cannot be said of œsophagostomy ; and there is every reason to believe that the successes will become more numerous if it is resorted to as soon as the diagnosis of the disease has been made, and before the powers of the patient are materially impaired. The few deaths do not constitute an argument against its adoption ; while "every recovery is a clear gain, and a fatal issue is simply the natural termination forestalled." The operations which have been practised for cicatricial stricture are gastrostomy, œsophagostomy, internal œsophagotomy, combined œsophagotomy, and retrograde di-

vulsion. Dilatation, Dr. Gross holds, is merely a palliative remedy, and sufficient time has not yet elapsed to test the value of divulsion through an opening in the stomach. Combined œsophagotomy for strictures near the cardia is only applicable to children, and may prove of value in strictures impassable by instruments introduced through the mouth. Internal œsophagotomy, if performed at all, should be reserved for comparatively recent and short strictures, and œsophagostomy is only applicable when the incision can be made below the obstruction. Gastrostomy, he holds, is the best and safest operation for simple stricture of the œsophagus. From the great difficulty of managing cicatricial stricture in children by dilatation, which is due partly to the struggles of the subjects and partly to the disinclination of the parents to distress the child, Dr. Gross holds that dilatation should be resorted to only when the inflammation has subsided and the denuded surface is in a granulating condition. When the constriction is of some standing, and efforts at dilatation prove fruitless, gastrostomy will prove to be the safest and most beneficial operation for prolonging life.

Theories of Color-perception.—Dr. Swan M. Burnett, of Washington, D. C., discusses the various theories of color-perception, and points out that none of them accounts, in a consistent manner, for all the phenomena of normal and abnormal colored vision, and that, moreover, there are certain objections on physical grounds which, with our present knowledge of the laws of molecular and wave-motion, are insurmountable. He advances a theory which, he thinks, meets the requirements of the case in the light of recently acquired knowledge. He holds that it is essential to do away with the idea of the retina as a differentiating organ, and that it should be looked upon simply as receiving and transmitting structure which shall give up faithfully to the optic nerve the impressions made upon it by the waves of the luminiferous ether. These impressions are carried by the nerve to the brain, and are there properly differentiated and converted into sensations. He believes that by this means all the phenomena of color-perception and color-blindness can be explained in a natural and consistent manner without the necessity of imagining new tissues, or novel or unusual reactions of these tissues to light. Dr. Burnett considers the retina to be a substance whose ultimate structure is such as to allow it to respond at one and at the same time to a large number of ethereal vibrations; at least such a number as shall be represented by the clearly distinguishable colors of the spectrum.—*American Journal of the Medical Sciences*, July, 1884.

A Case of Tubal Pregnancy.—Dr. Henry Hun, of Albany, records, in *The American Journal of the Medical Sciences* for July, 1884, a case of tubal pregnancy, in which the cyst burst at about the twenty-fifth day, and the patient died. Dr. Hun obtained the specimen, and after having rendered the embryo transparent by oil of cloves, carefully studied it and made an accurate drawing of it. In this case the ovum was in the right Fallopian tube and its corpus luteum was in the left ovary. In a considerable number of cases of tubal pregnancy the corpus luteum is found in the ovary of the other side, and it is very possible that this unusual origin of the ovum may be the cause of the tubal pregnancy, for if the tube bends over and reaches the opposite ovary it will be apt to be so bent and twisted that the ovum will meet with great difficulty in passing through it, or, if an impregnated ovum passes across the pelvis and enters the tube of the other side, so much time will be consumed in its journey that it may develop to such a size before it gets to the uterus that it cannot pass through the tube, and will continue its development in this organ. This is the only cause which can be assumed in Dr. Hun's case, for there was no occlusion of the tube by tumors, bands of adhesions, or displacement of the uterus, as are sometimes found in these cases; neither was there any great fright or emotion experienced at or near the time of sexual intercourse, which, in a number of such cases, has appeared to cause the extra-uterine pregnancy.

Unilateral Swelling of Hysterical Hemiplegia.—Dr. S. Weir Mitchell records, in the July number of *The American Journal of the Medical Sciences*, three cases of hysteria, in which there was unilateral increase in bulk at or near the menstrual period, and also at other seasons, after emotional excitement, and he has been unable to find elsewhere any narration of similar cases. Whatever conclusions we may reach as to the immediate cause of the unilateral differences in size, which Dr. Mitchell has here described, it is at least clear that they are under the influence of the nervous system, and vary with the causes which also increase or lessen the analgesia, or give rise to chronic spasm. Beyond this Dr. Mitchell can as yet hardly go. Most probably, he thinks, it will be found that in many unilateral hysteric palsies a like phenomenon exists, and has merely escaped attention because of being the least prominent in a group of symptoms. At all events, it adds another to the large group of resemblances which so closely relate organic to hysteric hemipalsy.

Treatment of Ingrowing Toe-nail.—Professor Petersen removes the whole of the soft parts down one side of the nail, extirpates the nail itself, from antiseptic motives, and, after arresting bleeding by pressure, dresses the wound rapidly with oxide of zinc and cotton-wool. Fourteen days' rest in bed, with the foot raised, generally suffices for cure, and the contraction of the cicatrix prevents a relapse to the old condition. Professor Petersen prefers general to local anæsthesia, on account of the troublesome bleeding afterward; and for the same reason he does not approve of Esmarch's bandage in this operation.—*Cin. Lancet and Clinic*, June 14, 1884.

Massage in the Treatment of Stricture of the Urethra.—The difficulty of passing a sound in stricture of the urethra following gonorrhœa depends, in the majority of cases, not so much upon the simple narrowing of the urethra itself as upon proliferation of the connective tissue in the surrounding parts. This hyperplasia of the connective tissue occurs in irregular patches about the urethra in such a way as to render the canal tortuous, thus increasing the difficulty of passing an instrument to the bladder. Dr. Géza v. Antal relates a number of cases (*Centralblatt für Chirurgie*, June 7, 1884) in which he succeeded in inducing absorption of this hyperplasia by massage. The duration of each sitting was from eight to ten minutes, and the massage was repeated daily. Massage of the pendulous portion of the urethra presents no difficulties, but that of the membranous and prostatic portions is possible only through the rectum. Internal massage by means of the repeated introduction and withdrawal of a sound, as recommended by Bardinet, does not commend itself to the author. It is only possible in those cases in which the stricture is already permeable, while v. Antal's method is of especial value precisely in those cases in which the urethra will not admit of the passage of a bougie. Further than this, internal massage acts only upon the thin layer of tissue immediately surrounding the urethra, while the external method causes the entire hyperplasia to disappear. The author thinks that in many cases massage will be used in preference to urethrotomy.

Rabies in Birds.—M. L. Gibier has succeeded in inoculating hens with the virus of hydrophobia and then reinoculating rats with cerebral matter taken from these diseased birds. The rats so treated presented all the characteristic symptoms of rabies; microscopic examination of the brains of the inoculated hens showed the presence of the specific micrococcus.—*Centralblatt für Chirurgie*, June 7, 1884.

Death following the Extraction of a Tooth.—Dr. Zakharevitch relates two instances of young men, both physicians, dying from the results of the extraction of a molar tooth. One died ten days after the operation from osteomyelitis, and the other six days after from osteitis of the inferior maxilla and septicæmia. It was found that the dentist had not been careful in cleaning the forceps used by him. The author, moved by these accidents, recommends the employment of antiseptic tooth-pulling. He advises washing the inside of the cheeks with soap and water, and then with a two per cent. solution of carbolic acid. After the tooth has been extracted the mouth should be again washed with the carbolic solution and the tooth cavity filled with a wad of cotton charged with iodoform powder.—*Raccoglitore Medico*, June 20, 1884.

Treatment of Slight Burns.—Dr. Cramer treats slight degrees of burns by means of compression. He applies a layer of wadding and over this an elastic bandage, so as to make firm and even pressure over the whole of the injured surface. By this means the subcutaneous capillaries are emptied in a measure of their blood, and inflammation and exudation of serum are prevented. The compression is to be maintained from three to fifteen hours, according to the intensity of the burn, and then a less degree of pressure kept up until new epidermis has formed.—*Memorabilien*, May 14, 1884.

Treatment of Sweating of the Feet.—The following method of treatment for this unpleasant condition is endorsed by Dr. G. Cramer in *Memorabilien* of May 14, 1884. The patient must wash his feet thoroughly in a two to five per cent. solution of carbolic acid, at first twice a day, then once a day, and finally two or three times a week. After the bath he is to put on clean stockings, sprinkled inside and outside with a powder composed of two parts benzoin, three parts salicylic acid, and ninety-five parts magnesia. The shoes must also be sprinkled inside with the powder. The stockings, when taken off, should be allowed to soak for twelve hours in carbolized water, then dipped in lye, and washed. In this way the bacteria which cause the skin affection and the consequent abnormal secretion of sweat are destroyed. Without this thorough disinfection, Dr. Cramer maintains, a cure of the affection is impossible.

The Apyretic Form of Typhoid Fever.—Dr. Brothier has collected several observations, which show that in certain cases the characteristic lesions of typhoid fever may be found in patients whose temperature has always remained normal. In spite of the apparent mildness of the disease, hemorrhages, perforation, and other complications are liable to occur. The symptoms are those of the ordinary form, with the exception that they are less marked, and that the temperature does not rise above the normal standard. It is very important to keep the patient in bed, and the diet must be carefully regulated.—*Jour. de Méd. et de Chir. Prat.*

Reunion of Divided Nerves.—Nerve-suture is often unsuccessful, especially in those cases in which a portion of the nerve has been excised, the tension causing the sutures to cut their way out. For this reason Dr. A. L. Rava, of Kieff (*Centralblatt für Chirurgie*, June 7, 1884), has discarded this method, and instead simply brings the divided ends of the nerve so that they overlap, and then ties them together. He has found by experiments upon more than a hundred animals that the conductive power of the nerve is perfectly restored. After exposing the nerve-sheath, and before dividing it, he passes two catgut ligatures beneath it, and ties them tightly enough to prevent slipping. The nerve is then divided, and the two ends, after flexing the limb so that they may overlap, are tied together. After the expiration of from six to twenty months, experiments were made to test the conductivity of the nerves, and in every case the muscles responded readily to central irritation of the nerves. In some cases he divided two nerves and reunited them in crossed fashion, so that the peripheral end of one nerve was attached to the central extremity of the other. Then, after allowing sufficient time to elapse for union to occur, he found that central irritation of one nerve was followed by a response in the muscles attached to the peripheral extremity of the other nerve with which the first had been united. This was conclusive proof that union between the two divided nerves was perfect. The author believes that his method will be found of especial utility in those cases of gunshot wounds and the like in which there has been a considerable loss of nerve-substance, and which are precisely the cases where suture of the divided ends is impracticable. In operations also in which a number of nerves or a plexus has been divided, the various ends may be tied together without regard to preserving their separate identity, in the expectation that the functions of all the wounded nerves will be restored.

Miliary Aneurisms of the Mucous Membrane of the Stomach.—Dr. Gallard reports (*Gaz. Hebdomadaire*) the case of a man, forty-eight years of age, who was admitted into the hospital in a state of extreme prostration, caused by repeated hemorrhages from the stomach. There was anorexia, and pain in the epigastric region, but no local or general disease could be made out. The patient died after a few hours, and at the post-mortem examination an aneurism of the size of a bean, situated near the cardia, was found to have given way. Gallard has observed two other cases of the same affection, and thinks that the so-called essential hæmatemesis is generally caused by the rupture of a small gastric aneurism.

Left Inguinal Colotomy for Imperforate Rectum.—Dr. W. H. Haynes, of New York, records in the July number of *The American Journal of the Medical Sciences* a case of inguinal colotomy. One procedure in the treatment we do not find discussed elsewhere in detail, namely, that of opening up a passage at the natural site for the canal, either simultaneously or subsequent to the operation of opening the gut. When the two operations are to be performed at the same time, the first or inguinal opening would be in the nature of an exploratory operation, and should be made small so as to admit of immediate closure, and return to the peritoneal cavity after a passage had been secured at the natural site. If this latter be not secured, then the opening could be enlarged and made to serve the purpose of an artificial anus in the abdominal wall. The advisability of this procedure, however, is at present in such a doubtful state that only the experience of a number of operators can determine it. Of the few cases so far undertaken in this manner that Dr. Haynes can find recorded, his own is the only one that survived the second operation. Dr. Haynes' single experience, though successful, does not lead him to advise this procedure, since the object of it will, during the early years of its life, be dependent on the exceedingly diligent and constant attentions of others whose affections and services, though the closest, are not to be depended on, as was demonstrated in his case. If the second operation be subsequent to the first, the patient will have a double annoyance, or be under the necessity of having a third operation performed for the closure of the opening first made, which is not unattended by danger to life or of doubts as to the result; and perhaps be under the necessity of having to have it reopened, owing to neglect in the proper after-treatment of the new canal in the natural site. Whereas if one is satisfied with having saved life in a manner which numerous cases testify is not unenjoyable or full of discomfort, as used to be maintained, all dangerous risks of subsequent operations are avoided, there will be no more dependence on others' services than is natural, and many sources of distress will be obviated.

THE MEDICAL RECORD:

CHOLERA AND THE CABINET.

THE approach of cholera along the great routes of European emigration to the Northern ports, and the ever-threatening presence of yellow fever along the lines of commercial intercourse between tropical countries and the Southern ports, places the United States this season in a peculiarly dangerous position with reference to those foreign pestilential diseases. So eminent an authority as Koch is reported to have stated, after personal examination of cases at Toulon, that the disease is genuine Asiatic cholera, and of the most unmanageable type, and that it would spread everywhere. This statement is in accordance with our own convictions, as stated in a previous article, in which we took occasion to urge our health authorities, and especially those of the large seaport towns whither emigration tends, to take immediate steps both to effect thorough sanitation and to vigilantly watch the current diarrhœal affections. As to yellow fever, no predictions can be made; it is a summer pestilence which is ever at our doors, and only awaits favoring conditions to invade our Southern seaboard cities. Of this, however, we are reasonably certain, viz.: that the United States is threatened with two foreign foes, the most fatal to public health and national prosperity of any known, both of which it is in the power of a properly organized and equipped sanitary service to prevent. The progress of cholera since our last article confirms our prediction that we are imminently threatened with an outbreak of this Oriental plague, and we urgently advise all local boards of health to organize their methods and forces as if in the very presence of the epidemic. We repeat what we then said, and with added emphasis, that no intelligent health authority will rely on our present quarantines to prevent the introduction of the germs of that disease into this country. If the epidemic is rendered in any sense harmless, and is brought under any proper control, it will be by the vigorous and vigilant action of local boards of health. We are gratified to notice that the New York State Board has issued the excellent memoranda prepared by its late Secretary, Dr. Elisha Harris, and that other State Boards have taken similar action.

In this approaching conflict with a foreign foe, more dangerous to the health and prosperity of the people than a European army, it is pertinent to inquire what is the attitude of our Government toward this national scourge? With the first rumor of cholera in Toulon, the Governments of Europe summoned their Boards of Health to prepare regulations and to take immediate measures to prevent an invasion of the epidemic. Among those brought into the service of their respective States, we notice the names of the eminent sanitarians Koch and Pasteur, of Brouardel and Prouse, of Buchanan and Carpenter. But what action has our Government taken to protect the country now on the eve of invasion by two of the most terrible scourges known to the human family? Though it has in its service a National Board of Health, composed of experienced physicians and sanitary experts, the duty of which is, according to the statute, "to obtain information upon all matters affecting the public health, to advise the several departments of the Government . . . on all questions submitted by them," we cannot learn that the advice of this Board has been sought in this great and pressing emergency, on any question relating to the approaching epidemics, by any department of Government. It appears that the Cabinet had a meeting on Saturday, and "it was decided to take prompt measures to prevent the introduction of cholera into the United States; the State and Treasury Departments will act in conjunction in enforcing the regulations to be prepared." What member of the Cabinet is sufficiently familiar with the latest discoveries of science and the teachings of experience in the control of cholera to prepare these "regulations," does not appear. In the Cabinets of Europe no one has been found competent to prepare "regulations" to meet the demands of modern science in the prevention of cholera, and hence those Governments at once called to their aid their several National Boards of Health, and submitted to them all questions relating to the prevention of the epidemic. But with an assurance peculiar to the Yankee nation, our Cabinet ignores the branch of the public service constituted by law its adviser on all matters pertaining to the public health, and single-handed grapples with and settles, to its own satisfaction, questions of science which the foremost medical men approach with special care and caution. If we may judge of the character of the "regulations" in course of preparation by the daily bulletins from the Capitol, or from the President's Proclamation, we should infer that the Cabinet had consulted some antiquated authority—a resident of Venice in the fifteenth century. As yet the Government has proposed no measure at all adequate to the emergency, and is evidently entirely unaware of its duties and its obligations. Its reliance seems to be on daily bulletins issued to the Associated Press and a proclamation by the President.

Well-meaning as undoubtedly these efforts of the Cabinet are, we venture to suggest that they are altogether unworthy the age and the occasion. If no better counsels prevail in the Cabinet, cholera will invade our shores and spread far and wide, except as it is stamped out in localities by energetic and enlightened boards of health, and the money appropriated by Congress will melt away, leaving no record of great achievements in the prevention of the epidemic.

We make these remarks in no captious or cavilling spirit, but with a painful consciousness that in the struggle among nations to combat this common foe of the human race, our Government lags far behind. It enters upon a warfare discarding the very arm of the public

service created for the occasion, and fully qualified to give it the highest degree of success in the field of conflict. Much as we lament the occurrence of a great epidemic, which leaves only misery, ruin, and death in its path, we still recognize the fact that every such devastation brings us nearer to the golden era when no contagious or infectious disease will be allowed to travel along the highways of commerce and human intercourse. The yellow fever epidemic of 1878 was a national calamity, but it did more to organize a system of sanitary service in this country than would a century of agitation by simple agreements and appeals. Six years of freedom from epidemics has created an indifference to health organizations which has, in many instances, ripened into actual hostility to their existence. It requires other great epidemics to restore these organizations to the public confidence and perfect their methods of work. That these epidemics will come, as great public educators, at proper intervals, until our system of sanitary government is perfected, we need not doubt. We look hopefully forward to the time when sanitary science, thoroughly and intelligently applied by national, State, and municipal governments, will eliminate from our mortality records the names of all contagious and infectious diseases.

THE TREATMENT OF DIARRHŒA.

A CONSIDERATION of the commonest diseases acquires a special interest at different times. At present as we are in the midst of the heated season, with cholera just on the edge of the horizon, it may be of interest to discuss such a familiar subject as the treatment of diarrhœa. All recognize that a diarrhœa is simply an expression of a certain derangement of the gastro-intestinal tract. To interpret and remove the cause should be the first rational effort of treatment. Now as the vast majority of gastro-intestinal disturbances are produced by indigestible food, a diarrhœa is very frequently at the start a conservative process induced by nature to get rid of such an offending mass. In the efforts to achieve this object a catarrhal inflammation is often set up. The idea of treatment should be to so expedite the removal of the foreign substance as to save the intense irritation involved in nature's unaided efforts to accomplish this end. In these days, lobsters and green apples, clams and cucumbers, are among us. Their digestion is frequently assisted by ice-cream; nearly always by large quantities of ice-water. Just as the unfortunate stomach is trying to get warmed up to its difficult task, its temperature is suddenly and greatly lowered by a deluge of ice-water. This is repeated so frequently that finally the injured viscus gives up in despair and passes the unchanged material along to the intestine to get rid of it as best it may. It is fortunate for the patient if the doctor, in his zeal to check the naturally induced purging, does not suddenly lock up the bowel, and in it the offending matter that is causing all the trouble. There is a popular idea that a diarrhœa should not be stopped too suddenly. As there is nearly always a grain of truth somewhere to be found underlying a popular delusion, so this idea doubtless rests upon the fact that an intestinal discharge due to irritating masses of food, suddenly checked by a heroic dose of opium, may be followed by inflammation of the bowels and peritonitis. When such a source of irritation has been removed, a diarrhœa cannot be checked too quickly. Indeed, further treatment is frequently unnecessary. The elimination of indigestible substances can be accomplished by various agents. All irritating laxatives must be avoided. A few grains of calomel finely triturated with a little bicarbonate of soda and sugar of milk often does very well. A small dose of calomel if triturated finely enough, will answer all the purposes of a large amount. Many physicians prefer castor-oil or some of the preparations of rhubarb for cleaning out the bowel. The secondary astringent effects of these drugs are beneficial. It is well to combine with them a small quantity of one of the preparations of opium. After the irritating cause of a diarrhœa has been removed, the different astringents can be used, according to the preference of the practitioner. Out of a very large number from which to choose, the sub-nitrate of bismuth in large doses is probably the least harmful and most effectual. It checks any acid fermentation, and soothes and constringes the mucous membrane.

While improper food is a preponderating element in the diarrhœa of summer, impure water and foul air introduce into the system noxious ingredients that are frequently irritating to the bowel. It is a common experience of medical students to contract a diarrhœa from staying in the dissecting-room, which ceases when they stop working upon the cadaver. A conservative process of elimination is here instituted that probably saves them a fever. Animal and vegetable refuse matter in the streets, wakened into active fermentation by the hot sun of summer, may act the same upon the layman as the dissecting-room does upon the students. Some persons seem to be peculiarly susceptible to this form of poison, and correspondingly quick to throw it off by a diarrhœa. The treatment of this form of intestinal derangement is obviously to remove the patient from exposure to the foul air, when recovery will readily take place. Mild astringents may be needed to hasten this result. Occasionally persons in debilitated condition, in consequence of the heat and impurity of air so frequently found in the city in summer, seek to relieve a continual irritation of the bowels by a change to the purer air of the country. But if the air is purer, unfortunately often as much cannot be said of country water. In fact, many people leaving town in a sound condition fall victims to diarrhœa before many days' sojourn in the country. The uncomfortable proximity of the cess-pool to the well, and the defective means of ridding the premises of sewage, destroy the good effects of many a rural visit. The sanitary condition of numbers of farm-houses and country hotels is far from what it should be. If the visitor does no more than contract a diarrhœa in many of these places he will be fortunate. Of course a simple change in the character of drinking water often produces a slight diarrhœa, aside from any animal or excess of vegetable matter it may contain. If a looseness of the bowels persists, however, after treatment by ordinary astringents, the patient had better quickly change his place of summer recreation. The valuable account of the sanitary condition of health resorts, appearing in the report of the National Board of Health for 1882, affords interesting reading on this subject.

We have thus seen that a diarrhœa is primarily a conservative process of nature indicating its efforts to eliminate some disturbing element in the economy, and that during the present season, indigestible food, bad air, and impure water, under the debilitating influences of high temperature, are most frequent causes in its production. Any looseness of the bowels must always be treated directly in reference to the agent producing such condition.

In an article on another page of this number Dr. Chapin has called especial attention to the fatal effects of great heat in largely increasing the mortality from infantile diarrhœa. As shown by his statistics, susceptibility to a high temperature is much greater in early life than in adults.

In conclusion, the laity should have impressed upon them the great importance of attending at once to any looseness of the bowels at this time. A diarrhœal condition of the intestine is a favorite developing place for the comma-shaped bacillus that Dr. Koch is just now finding in the bowels and dejections of cholera patients. Every possible means should be taken to avoid affording a favorable soil for this bacillus, in case it finds its way to our shores. It is certain that it will not stay long if it finds a limited field for its development. The possibility of such an invasion is suggested by the fact that a ship has lately arrived in lower quarantine from Marseilles, laden with a cargo of wool.

MEDICAL CHARITY IN THE SOUTH.

We publish elsewhere a communication from Dr. Sheardown, of Knoxville, Tenn., in which he goes over the familiar ground of the abuses of medical charity. It is interesting as showing the state of things in the smaller cities throughout the West and South; and also because the author makes some suggestions as to remedies.

Dr. Sheardown is a trifle one-sided in his description of the status of medical charity. It is to be remembered that a large amount of medical service is tendered for the sake of learning or teaching. Medical students and young practitioners must be educated and must learn their art practically. They are, therefore, glad to work in hospitals and dispensaries for nothing. In smaller cities and towns, to be sure, where medical colleges do not exist, this factor does not come in to so great an extent.

We think that it would be better also that the profession earn less money, rather than gain the reputation of being hard-fisted, and always demanding the *quid pro quo*. We say this while fully aware that Dr. Sheardown has in the main presented the question correctly.

SOME PRACTICAL FACTS REGARDING ASIATIC CHOLERA.

As to its nature and mode of prevention.—Asiatic cholera requires for its development, first, a specific germ of poison; second, a proper soil for the poison to grow in. We may not be able to keep away the germ by quarantine, but we can destroy the soil by disinfectants.

"Excrement-sodden earth, excrement-reeking air, excrement-tainted water," these are for Americans the causes of cholera.

Cholera attacks the most insalubrious places in a city in succession. Hence every man can choose whether he will live in a nidus for the disease or not.

The poison of cholera exists in water, and wet soil chiefly, also in food, and in the air near infected spots only. It has a very short reach. It is infectious and portable, but not contagious in the ordinary sense. Hospital attendants, nurses, and doctors, if careful, are but little more liable to the disease than others living in the same locality.

Koch's cholera bacillus, if really a pathogenic agent (which has not yet been proved), is only one of the factors necessary to develop cholera.

Maritime quarantine is of use in preventing cholera. Inland quarantine and sanitary cordons are of no value. To keep clean is the best internal quarantine.

The best disinfectants for cholera are carbolic acid, the zinc and copper salts, and corrosive sublimate.

There are no specifics against the attacks of cholera, except perfect domestic and personal cleanliness, temperate living, and leaving the infected spot.

The French have an old "preventive of cholera" which runs as follows:

> "Tiens tes pattes au chaud,
> Tiens vides tes boyaux,
> Ne vois pas Marguerite,
> Du choléra tu seras quitte."

The prevalence of typhoid fever furnishes a fair indication of the extent to which cholera would spread if it reached a city. Such is the conclusion of English observers. There is very little typhoid in New York City now.

Persons living in low-lying parts of a city or town are the most liable to cholera. The inhabitants of high flats, properly plumbed, are safe.

Panics over cholera, such as occurred at Toulon and Marseilles, show ignorance as well as cowardice. Modern sanitation can hold cholera in check.

The *mortality from cholera* does not average over fifty per cent. It is generally less toward the close of an epidemic. The mortality is less in those treated in hospitals (in England). The mortality rate varies somewhat with each epidemic.

The *duration of a cholera epidemic* in a given community is several months, unless it is "stamped" out by sanitary measures. It may go away and return again the next year. In any limited locality it expends its force in two to three weeks.

Of individual cases, the duration, if fatal, is about two and one-half days, if non-fatal, about nine days. The period of incubation of cholera is from two days to a week.

Diagnostic points.—Painless, profuse diarrhœa should excite suspicion. A case showing such symptoms as non-feculent, very copious, watery stools, of a rice-water character, early cramps, quick exhaustion, low temperature, pinched facies, should make the physician very suspicious. If cholera were present in the locality his diagnosis could be positive.

Points in treatment.—Epidemic cholera is generally preceded by a painless diarrhœa. This, if attended to at once, can be easily cured in ninety-nine per cent. of the cases. Hypodermic injections of morphine, and the internal use of opium, aromatics, and astringents, are indicated here. In the collapse stage of cholera give ice-water and ice, but be careful in the use of stimulants.

Watch the pulse to see if they affect it. Horner's anti-cholera mixture, recommended by Hartshorn and Bartholow, may be used before or at the beginning of the stage of collapse.

℞. Chloroform,
Tinct. opii,
Spts. camph.,
Spts. ammon. aromat .....āā f ʒ jss.
Creasote..... gtt. iij.
Olei cinnamomi..... gtt. vij.
Spts. vini gall..... f ʒ ij.

M. Sig.—Gtt. x. to xx. in ice-water every five minutes.

A hypodermic injection of morphine is a most effective remedy for the diarrhœa and cramps.

Cholera specifics do not exist. Oxygen, saline venous injections, chloride of sodium drinks, warm baths, calomel, camphor, venesection, have all failed.

TIGHT CESSPOOLS, THEIR DANGERS AND REMEDIES.

We so frequently receive letters like the subjoined, that we have concluded to answer once and for all, at least for the present, in our pages:

Long Island, June 19, 1884.

Dear Sir: May I ask a favor at your hands? The water-closets in my house discharge into a cesspool of about two thousand gallons capacity. This is of brick, well cemented, and supposed to be tight; it is closed by a stone slab and has no ventilation. Its contents are pumped out and put upon the land as often as once a month in the summer, and in winter, when full, say about once in three months.

In my water-closets the bottled chlorides are freely used, but I have come to suspect that the quantity used is not sufficient to disinfect the cesspool. The arrangement of the plumbing, soil-pipe, etc., I believe to be good.

Should this cesspool be treated with additional disinfectants? If so, how often, and when? When full, or when just emptied, or more frequently? Can you also give me an idea what quantity of, say a saturated solution of copperas, or anything else which you can recommend as better, should be considered enough for one application? I mention the strong solution of copperas because I am familiar with it, and always keep the solid salt by the barrel on hand for frequent use about my premises, stable, etc. It is cheap and in convenient form for solution. Is there anything better? How about carbolic acid, quicklime, sulphur, etc.?

Yours very truly, G. T. L.

The readers of The Record need scarcely be told that tight and unventilated cesspools, with no outlet for their gases except into the bath-tubs, water-closets, wash-basins, and kitchen-sinks, which empty into them, must rank among the most dangerous of all "modern conveniences" that can be devised by the perverse ingenuity of man. They are far more dangerous than open privies, open cesspools, and more or less ventilated sewers. The gases which are formed, and the germs which are bred, in darkness and heat, with little or no oxidation or renewal of air, are among the most concentrated and virulent; far more injurious and destructive than ordinary sewer gases, which always have so many outlets to the open air. A closely sealed cesspool is a many multiplying foul air-chamber or foul gas-retort. Apart from the ordinary unsavory and harmful products of the decomposition of vegetable and animal matters which takes place there, all the discharges from patients sick with measles, scarlet fever, diphtheria, summer diarrhœa, dysentery, or typhoid or intermittent fever, if there happens to come any, also become more virulent. Yet just such cesspools are among the most common additions to the largest and finest country houses, and are regarded as the nicest things for country hotels and summer boarding-houses. They are very numerous in the most fashionable watering places. It is not uncommon, in some half-primitive and half-civilized places, to find out-door privies for the male boarders and up-stair water-closets for females, the pipes from which empty into a tight cesspool. In order to save a few hundred feet of drain-pipe these cesspools are generally placed very near the houses. Every observant person has seen them within ten feet, more or less, of parlor or bed-room windows, with huge and even splendid flower-pots put over their covers, in order to hide any trace of their existence. Of course, these hotel and boarding-house cesspools cannot be emptied during the summer season, when the gases and germs in them become abundant and virulent, and have no escape except into the rooms from which the materials for their growth and composition came. When consulted about such matters it is well to advise that a new cesspool be built far away from the house. It should have a large man-hole, which should always be left open for free ventilation; then such great quantities of fresh earth should be thrown into it from time to time, that not only all fluids and moisture should be neutralized and absorbed, but all its foul contents should be covered by at least six inches of fresh absorbent earth. In short, the cesspool should be converted into a great and wholesome earth-pit. Thus not only will the whole contents be kept odorless and healthy, but all the waste materials of the house will be changed into an excellent and inoffensive fertilizer, which can be used in gardens as well as fields. Every open out-door privy can be changed, in the same simple and inexpensive way, into an outdoor earth-closet by throwing in, if necessary, one or several or many cart loads of fresh earth, until a dry surface of earth alone is visible, and all offence to the eye and nose is obviated. Then fresh earth should be thrown in every day, sufficient to hide and disinfect the daily deposits. We are sure that this earth treatment of cesspools and privies would pay in the greatly increased quantity of excellent and inodorous fertilizers which would be gained; for earth permeated with the fluids and gases of decomposition is almost as rich as garden mould.

It requires no stretch of imagination to suppose that it would pay to have earth thrown from time to time in every horse-manure pit, and over the contents of every stable- and barn-yard. Horse, cow, and cattle manure would thus be ripened and mellowed. The great waste of good material by evaporation from the heat of the sun in the hot months, and by the washing and soakage of rain in wet times, would be largely prevented. An enthusiastic hygienist says, every country barn- and stable-yard could be converted into a wholesome and cleanly earth-yard, where every one could almost always walk with comfort and decency. The nasty smells of stablemen, and cow and cattle herdsmen would also be largely done away with. Many of the diseases which arise from the discharges of sick men, horses, and cattle would be pre-

vented; the occupations of stable and cattle men, and even sweet milkmaids, would become much more cleanly and wholesome. The amount of good and savory fertilizers that would be gained would be almost incalculable. The air of every country house, village, and small town would be greatly improved. Places naturally wholesome, but polluted by thoughtless man's filthy habits, would regain their primitive healthfulness. We have heard of pleasant and productive farm-yards which were hollowed and graded toward the centre to prevent all fluids from running off to waste. The bottoms were stamped down hard to make an impervious base, over this about six inches of loose earth was thrown, and above this the first layer of the droppings of horses or cattle or both were thrown, also to the depth of six or more inches; then a fresh layer of earth, say three inches, and so on successively, layer by layer of earth and manure. Such farmers always had much more and better fertilizers than their neighbors. Their barn and stable yards were always pleasant and wholesome, their stable and cattle men and women were always more tidy, sweet smelling, and cleanly. The milk and butter was better, and spoiled less readily; almost all infectious human, horse, and cattle diseases were prevented or quickly stamped out, and that without other scientific or chemical aid.

News of the Week.

The Greely Arctic Expedition.—The reports from this expedition show that Americans can live for two years in perfect health in the arctic region, and that the use of brackish water does not produce scurvy.

A New Insane Asylum for Iowa.—A new asylum for the insane is to be built at Clarinda, Iowa. The sum of $50,000 has been appropriated for beginning the work.

Journalistic Changes. — Dr. T. F. Rumbold has given up the editorship of the *St. Louis Medical and Surgical Journal*. Dr. Le G. Atwood becomes editor in his place.

Dr. R. B. Stover has retired from the editorship of the *Atlantic Journal of Medicine*, leaving it in charge of Dr. Henry G. Houston.

Dr. Wesley C. Norwood, a prominent physician of South Carolina, and a medical writer of note, died at Cokesburg, S. C., June 17th, at the age of seventy-eight. Out of a handsome competence he gave magnificent gifts of money to Wofford College, South Carolina, and Adger College, South Carolina.

Dr. Kirkbride's Successor. — Dr. John Bassett Chapin, Superintendent of the Willard Asylum for the Insane, at Willard, N. Y., has been unanimously elected by the Board of Managers of the Pennsylvania Hospital for the Insane to succeed Dr. Thomas S. Kirkbride, deceased, as Physician-in-Chief and Superintendent of that Institution. The Board is fortunate in having secured so able and accomplished a physician as Dr. Chapin.

The Yellow-fever Germ not Discovered.—Some months since considerable interest was excited by the announcement that Dr. Freire, of Rio Janeiro, had detected the presence of the organism causing yellow-fever in soil taken from graves of persons who had died from the fever, and that he had succeeded in communicating the disease to rabbits and guinea-pigs. But (*Medical Press and Circular*) in a communication since forwarded to the English Government from the island of Barbados an account is given of the results of a number of control experiments made with soil taken from the graves of persons who died of yellow-fever in the epidemic of 1881, and from open fields on which no manure had been used. Previously sterilized chicken-soup impregnated with any of these moulds and kept at the ordinary temperature usually became turbid in a few hours, and by the second day had assumed a bright yellow color. Summing up their results, Messrs. Moxly and Harrison say that they can discover no difference between a micrococcus from a grave and one from a garden.

The Legality of Cremation.—One of the English courts has just decided that it is illegal to cremate a body on which a coroner had determined to hold an inquest. The body in question was that of an illegitimate infant, and the decision seems an eminently natural and proper one.

A Grand Fair in Aid of the London Hospitals is, it is said, to be undertaken under the auspices of the Health Exhibition. The hospitals in question are, many of them, in great need of pecuniary help.

A Medical Drama.—A drama, called "Sister Grace," written by a doctor, and played for the benefit of the East London Hospital for Children, has just been presented at the Avenue Theatre, London. The play introduces hospital life and incidents. The binaural stethoscope made its first appearance on the stage.

The Death of Dr. Moreau, the celebrated alienist, at Paris, in the eighty-first year of his age, is announced. He was a pupil of Esquirol, and had been attached to Bicêtre and La Salpêtrière.

The Epidemic of Small-Pox, which has for some time been prevalent at Liverpool, has now attained alarming dimensions. Traffic, except for residents, is in certain streets suspended, and the public institutions for the reception of small-pox patients are full to overflowing. It is stated that the Local Government Board have severely censured the local authorities, and have called upon them to immediately provide suitable hospital accommodation for infectious cases. Small-pox is also still very prevalent in London, there having been over a thousand cases in the hospitals.

Excessive Child Mortality in New York City.—*The Lancet* estimates that the mortality rate among children under five years of age in New York City is 90.3 per 1,000 living children, while in London it is only 65.1 per 1,000, a difference of thirty-nine per cent.

The Yellow Fever Germ.—The Panama physician who claims to have discovered the yellow fever germ, to have cultivated and inoculated it, passed through this city last week on his way to Paris. He was interviewed by a member of the daily press, who procured a picture of the hypothetical germs and produced them before the admiring laity. As shown in wood-cuts, they certainly look like very ordinary forms of fungus.

Dr. Octave Pavy, Late Surgeon to the Greely Expedition, was a man of curious character, and had led a varied career. He was born in Havre, France, where he was educated, and where much of his youth was spent. Early in life he accompanied a French expedition to Lady Franklin Bay, and spent several years in the polar regions. He fought in the Franco-Prussian war. At its close he came to America, where he resorted to various expedients for a living. He finally studied medicine, and began practice in 1877. He was a member of the Howgate expedition, and when this failed he remained at Disco Island, off the coast of Greenland, until he joined the Greely party.

Dr. William Fruitnight, one of the medical staff of Bellevue Hospital, died suddenly, July 21st, at the residence of his brother, Dr. J. Henry Fruitnight, from thrombosis of the brain. The deceased was but twenty-five years of age. He was graduated from the Bellevue Hospital Medical College in 1880, and since that time had been attached to the medical staff at the hospital.

Professor Virchow has begun a series of popular articles on cholera in *Die Nation*, a weekly political journal of Berlin. He condemns the French for carelessness, and takes a conservative view as to the real significance of the cholera bacillus.

Medical Novelists.—Dr. William A. Hammond announces that he has four novels written, and intends hereafter to publish two a year. He states that he would rather be a novelist than a doctor, and thinks that it is time medical men, in a literary way, give some results of their rich and peculiar experience with human nature.

The Illinois State Board of Health held its quarterly session on July 2d. The Secretary in his report says: "There have been fewer complaints made direct to the Board, of unprofessional conduct, and fewer cases of this kind otherwise coming under observation, during this quarter than ever before in the history of the Board." Taking up the subject of public health, the Secretary refers to the prevalence of small-pox in England, and the probability that it will become more prevalent in this country. He advises the printing and distribution of the school vaccination order.

Pasteur's Experiments on the Prevention of Rabies.—Further experiments have been made by M. Pasteur on the prevention of hydrophobia by inoculation. He has experimented upon 57 dogs, 19 of which were mad, and 38 bitten by them under uniform conditions. Out of these 38, half had been previously inoculated. Those not inoculated died of unmistakable hydrophobia, whereas the 19 others are apparently in the possession of perfect health.

Death of Dr. Cæsar Henry Hawkins.—Dr. Cæsar Henry Hawkins, the well-known English surgeon, who had been Sergeant Surgeon to her Majesty Queen Victoria for a number of years, died in London, July 21st, at an advanced age. Dr. Hawkins was born near the close of the last century. After having served for a few years as Lecturer on Anatomy at the school in Great Windmill Street, London, he was appointed surgeon to St. George's Hospital, where he lectured on surgery, and rapidly became known as one of the most learned practitioners of Great Britain. He held this position for thirty-two years, in the meantime becoming a Trustee of the hospital, until 1861, when he resigned and was appointed consulting surgeon, a post which he filled until his death. He was also for several years an Examiner in Surgery at the University of London and a member of the Court of Examiners of the Royal College of Surgeons, of which he was twice elected President. He served at different times as President of the Royal Medical Society of England, the Royal Chirurgical, and the Royal Pathological Societies. On the death of Sir Benjamin Collins Brodie, Sergeant Surgeon to Her Majesty, Dr. Hawkins was appointed to fill the vacancy in the Queen's household. He was the author of a series of lectures on tumors, and furnished a number of other valuable contributions to medical journals.

Some Advanced Views on the Subject of Medical Education.—The Chicago Medical Society, says the *Medical Age*, has lately been devoting considerable of its attention to the subject of the regulation of medical practice in the State of Illinois, and a committee, recently appointed to place the matter in shape for consideration, has just made its report. The committee hold that no degree of the doctor of medicine should be deemed valid if conferred by any medical college on any one who shall not have been previously examined, as to his general education, by a committee of the school of practice which said student proposes to follow. They believe also that no medical college should hereafter be incorporated unless it have an endowment fund of not less than $150,000 free of all claims. They further believe that no person should be permitted to enter upon the practice of medicine unless he has been previously examined by a board of seven examiners on anatomy, physiology, chemistry, obstetrics, gynecology, surgery, practice of medicine, hygiene, State medicine, psychiatry, therapeutics, materia medica, and pharmacy. This board of examiners should be chosen from the various schools of medicine, in proportion to the number of practitioners of each school.

Cholera in the United States.—There have been five importations of Asiatic cholera into this country, viz., in 1832, 1848–49, 1854, 1865–66, 1873.

A Veritable Electrical Girl.—*A propos* of the Lulu Hurst nonsense, which has lately been amusing New Yorkers, Dr. Ch. Féré publishes editorially in the *Progres Médical* of July 5th the account of a genuine "electrical girl." He describes the case as one of the "electric neurosis." The patient, a woman twenty-nine years of age, had been under observation for three years. She was thin, anæmic, had a very dry skin, and suffered from nervous anorexia and ovarian tenderness. She appeared to be charged more or less with positive electricity. Her hair when stroked would crepitate, and sparks could be produced. With her fingers she could repel light (electro-positive) objects and attract others (electro-negative). She was in fine, in the condition of one who has been slightly charged with electricity. This evolution of electricity was much greater when her emotions were excited, and M. Féré appears to think that the force is evolved by Mme. X——, and not that it accumulates through friction in locomotion. In damp weather,

the phenomena are much less prominent, and when this is the case, the patient experiences lassitude and malaise. Static electricity given at this time makes her feel much better. M. Féré considers the condition the result of some neuropathic disturbance. He cites several somewhat similar cases reported by Drs. Girard, Mussy, Hosford, Floquin, and others.

Some of the Work which Cholera has Done.—In 1871 there were 300,000 deaths from cholera in Russia; in 1873 there were 16,000 deaths in Poland; in 1872–73 there were 140,000 deaths in Hungary; in 1872–73 there were nearly 27,000 deaths in Prussia; in 1865–67 there were 143,000 deaths in Italy. In Paris the mortality from cholera has been as follows: in 1832, 18,654 deaths; in 1849, 19,184; in 1853–54, 8,096; in 1865–66, 12,082; in 1873, 885. In England, in 1849, the deaths from cholera were 70,000. In 1817 the army of the Marquis of Hastings in India lost 9,000 men in twelve days from Asiatic cholera.

Progress of the Cholera in Europe.—At date of writing the cholera is continuing its ravages at Toulon and Marseilles with unabated violence. The deaths at the former place average daily between 20 and 30; at the latter between 50 and 60. The number of cases in the hospitals at Toulon averages about 200. The record for July 21st at the St. Mandrier Hospital was: admissions, 14; deaths, 2; under treatment, 122. We may infer that the epidemic is not a specially virulent one. Cases of Asiatic cholera are reported at Arles, at Nismes, and at Vienna. Deaths from "cholerine" are reported at Lyons. Deaths from sporadic cholera have been reported at Paris, but it is doubtful as yet if genuine cholera has reached that city. The French authorities have wisely decided not to undertake any inland quarantine against the disease, but to employ suitable inspection. Quarantine at the frontiers of Italy and Spain appears to have been carried out with a ridiculous, if not absolutely harmful stringency. Koch has presented to the mayor of Toulon a memorandum regarding the methods for preventing cholera. The substance of it is as follows: 1, cholera is propagated by people, and is generally communicated by contact with human beings or clothes; 2, lead a very temperate life, in eating as well as drinking; 3, see that your food comes from no infected locality—cook it well; 4, see that the water for drinking and washing is pure, boil it if need be; 5, avoid large gatherings, fairs, etc.; 6, disinfect choleraic evacuations with carbolic acid; 7, the apartments of cholera patients should be left uninhabited for six days; 8, persons who have been in contact with cholera cases should wash their hands in soap and water and carbolic acid; 9, laundresses should not take the linen of patients till after its disinfection; 10, the clothes of patients should not be transported until after disinfection; 11, funerals should be as plain as possible.

The French Government has decorated Koch with the cross of the Legion of Honor.

The National Dental Association held its fourth annual session in Washington, beginning July 22d. The President, Dr. R. B. Winder, of Baltimore, presided. We would suggest for future discussion the question, Why dentists always convene in hot weather?

The Importation of Rags into this Country from infected ports in Europe has been forbidden by the Government.

Suicide of Dr. William M. Dorran.—Early on the morning of July 22d Dr. William M. Dorran, of Mount Vernon, N. Y., shot himself in the head. He was dead when discovered. Dr. Dorran was born in Ireland, and was fifty-two years old. He graduated from the University Medical College in 1863. He left nothing telling why he had taken his life, but it is supposed that he became despondent over continued ill-health from a disease which he contracted in the army, while stationed at Fort Scott, Arkansas.

New Crematories.—Companies have been organized in Pittsburg, Pa., and Buffalo, N. Y., for the purpose of building crematories. They will conduct cremation on a business basis, and doubtless will find enough "cranks" to keep their furnaces supplied.

Peptonizing Milk—A Correction.—In Dr. Smith's letter on "The Feeding of Infants," etc., Medical Record, July 19th, p. 80, second column, it should read: "Mix a powder consisting of five grains of, etc.," instead of five grammes.

Final Decision Regarding the United States Medical College.—The Court of Appeals has declared that, according to the intent of our legislation, the words "literary or scientific college" in the amended general statute do not cover medical colleges, respecting the organization and management of which there is a special statute. The legal defect under which the "United States Medical College of the City of New York" labored from its birth not having been cured by the nicely planned legislation of 1882, that institution, says the *Times*, has returned to the nothingness out of which it sprang.

Is it True?—It is generally considered better not to wash in public the linen that is encumbered with adventitious, sordid, and germ-breeding products. Alleged peculiarities in the social habits of the American Medical Association doctors, however, have lately been receiving not only a national but a European laundressing. We clip the following from the *Medical Press and Circular*:

Lack of Refinement in the American Medical Association.—A resident of Washington writes to the New York *Medical Journal* as follows: "The usual disgraceful performances took place at the receptions. Mrs. L—— generously opened her beautiful house, and provided as fine a table as Demenet could serve. She was rewarded by having men stalk in (hats on their heads) from the front room to the dining-room, where they fought like wolves for places at the tables, overturning piles of plates, breaking her expensive ornaments, and soiling her rugs with pools of tobacco-juice."

We are very confident that the description thus given is a gross exaggeration. We have met a number of gentlemen who attended the Washington receptions and heard no such reports. We can refer also to the authority of the Texas *Courier-Record* that the members in question were a "grand, grave body of men," whose lives gave proof of the immortality of the soul, and suggested nothing of prandial rapacity and ill-timed expectoration. Washington correspondents should be a little more careful in criticising their medical colleagues.

Reports of Societies.

AMERICAN OTOLOGICAL SOCIETY.

Seventeenth Annual Session, held at Grand Hotel, Catskill Mountains, N. Y., July 15, 1884.

The American Otological Society held its seventeenth annual meeting at the Grand Hotel, Catskill Mountains, Tuesday, July 15, 1884.

Morning Session.

In the absence of the President, Dr. C. H. Burnett, Vice-President Dr. J. S. Prout called the Society to order.

The first business was the appointment of a Business Committee, consisting of Drs. F. B. Loring, E. W. Bartlett, and A. Alt.

Dr. Andrews, of Philadelphia, was invited to a seat in the Society.

Dr. H. Knapp, of New York, read a paper

ON THE INDICATIONS FOR OPENING THE MASTOID PROCESS, BASED ON SOME RECENT OBSERVATIONS.

In it he described three cases, which were cited as illustrations of some of the conditions in which this operation was of value. The first case was one of acute tympano-mastoiditis, in which paracentesis of the tympanic membrane had been tried without affording any relief. The mastoid process was trephined, a large amount of pus removed, and this was followed by rapid recovery. The second case was one of chronic suppurative tympano-mastoiditis, in which there was severe half-sided headache. In this case relief followed the operation. The third class of cases, of which an illustration was cited, was sclerosing mastoiditis. In this case the tympanic membrane was intact, there was constant severe headache. Complete relief was afforded by the operation.

The operation, as performed by Dr. Knapp, consists in making an incision one centimetre behind the insertion of the auricle, the point of election for perforating the bone being the pit of Dessarenne. Chisels alone are used in making the perforation. The direction of the opening should be parallel to the course of the external meatus. Especial stress was laid on the use of sponges in the cleansing of such wounds. The advantage being that no fibres are left in the part.

In acute suppurative otitis the immediate removal of the pus is sometimes sufficient to cause a cure. Syringing is not employed unless there is old suppuration or profuse suppuration sets in a few days after the operation. Where it is wished to have union by first intention, the edges of the wound are brought together with the continuous suture. This is intended after operations for merely congestive sclerosing processes, or when in non-suppurating otitis, the cranium has been opened.

For washing the wound, weak solutions of chloride of sodium or boracic acid are employed.

Before taking up the discussion of this paper, the paper of Dr. J. A. Lippincott, of Pittsburgh, Pa., was read, entitled,

A CASE OF MASTOIDITIS INTERNA CHRONICA WITH SCLEROSIS—TREPHINING—RECOVERY.

A young lady nineteen years old was first seen March 15, 1883, at which time she complained of moderately severe pain from which she had suffered several months. Her previous health had been good. The watch could be heard when placed against the ear. A quantity of wax was removed from the canal and the tympanic membrane found to be red and irritated. The removal of the wax did not cause much improvement in hearing, which was one-thirtieth in the right ear. The left ear was normal. Slight catarrh of the naso-pharynx was found. A solution of boric acid and borax was ordered to be instilled; this caused some relief. But five weeks later, the suffering greatly increased and the pain was referred to the region of the middle ear and to the mastoid process. It was also felt in the whole side of the head. There was a great deal of swelling over the process and below it. Examination of the ear showed that the membrane was not congested, but the typical light-cone was absent and the anterior two-thirds of the membrane showed a silvery lustre. The Eustachian tube was pervious. There was slight elevation of temperature. Leeching and poultices were applied externally, and calomel and a febrifuge administered internally. This caused rapid improvement.

The note of the case made April 28th was as follows: Continuous dull pain in the ear and mastoid process. The swelling has entirely disappeared. Hearing two-thirtieths. Tuning-fork on vertex heard best on the affected side.

During the following months the pain continued to increase in severity and was especially felt in the mastoid region. Hearing steadily diminished. There was no swelling, and cerebral symptoms were absent. The treatment consisted in the use of blisters, and other applications, incisions and anti-neuralgic and alterative remedies internally.

On March 20, 1884, an incision was made behind the auricle under ether, and an opening, seventeen millimetres in depth, was made with Buck's drill. The osseous tissue was hard and ivory-like. A carbolized tent was inserted and a poultice applied.

After the operation, the pain was greatly relieved and entirely disappeared in a few weeks. Shortly after the operation, a return of the pain was produced by exposure, but this was at once relieved by the application of an ointment of the yellow oxide of mercury and belladonna.

On July 8, 1884, the patient was entirely free from pain and the hearing was six-thirtieths.

Dr. A. H. Buck, of New York, thought that it was not desirable to attempt to obtain union by first intention. He had always believed that the good results of the operation were largely dependent on the irritation and drain which it produced.

Dr. Knapp said that the only case in which he had tried to secure healing by first intention was in one in which the lateral sinus had been opened.

Dr. Charles J. Kipp, of Newark, N. J., had come across a number of cases in which, while there was no external evidence of disease, carious bone was found after separating the periosteum, and cited an illustrative case.

Dr. Samuel Theobald, of Baltimore, Md., considered the administration of constitutional remedies a very important part of the treatment, often obviating the necessity for operation. He had obtained excellent results from the use particularly of iodide of potassium and the biniodide of mercury. With these he had used inunctions of mercurial ointment and the oleate of mercury.

Dr. Sexton, of New York, exhibited a number of photographs and briefly described the cases which they illustrated. He differed from Dr. Knapp in the conclusions which he had drawn. He did not think that pain alone was a sufficient ground on which to base a diagnosis of involvement of the mastoid process.

Dr. J. A. Andrews stated that one of the indications by which he was guided in opening the mastoid cells was the occurrence of swelling of the optic disk or optic neuritis. When this appeared in a case in which there was restlessness, and pain, he performed the operation.

Dr. A. Matthewson, of Brooklyn, stated that in many of the fatal cases of aural disease, post-mortem examinations failed to reveal any evidences of mastoid disease.

Dr. A. H. Buck described the method which he pursued in these cases. They can be divided into two classes: in one the mastoid disease develops in a well

person; in the other it develops in one who has had for some time a purulent discharge from the ear. If the disease supervenes in an old case of ear trouble, tenderness, redness, and swelling of the glands will probably be absent, although serious disease of the mastoid process is present. The next question is whether or not there is adequate provision for the discharge of matter. If there is not the operation should be performed. In the acute cases he considered it good surgery to operate on the mastoid process.

The paper was discussed further by Drs. Jones, Seely, Pooley, Mathewson, and Fryer.

Dr. A. H. Buck, of New York, in a paper

ON THE USE OF LARGE DOSES OF IODIDE OF POTASSIUM AND IODIDE OF SODIUM IN THE TREATMENT OF CASES OF RAPID LOSS OF HEARING

supposed to be due to syphilitic disease, reported several cases which he had collected in studying the literature of the subject. In two of these, benefit had followed anti-syphilitic treatment. He added to this a detailed account of a number of cases treated by himself with large doses of the iodides, in none of which had a cure been effected and in only one or two had temporary benefit been obtained. He had given the iodide in doses as large as five hundred and twenty-five grains per diem, without any beneficial effects. He thought that this was probably due to the fact that the disease had destroyed the organs essential to the perception of sound, and although the source of pressure which had caused this injury might be removed, the destruction had been such that the organ did not regain its functions.

Dr. Seely stated that his experience had led him to the conclusion that if benefit did not follow moderate doses of anti-syphilitic remedies it was not to be expected.

Dr. Buck had reached the same conclusion.

Drs. Mathewson, Jones, Knapp, and Andrews also took part in the discussion, and reported cases similar to those described by Dr. Buck in which the results of treatment had been negative.

Adjourned.

Evening Session.

The first paper read at the evening session was by Dr. Seely, of Cincinnati, O., on

THE TREATMENT OF SUPPURATIVE OTITIS MEDIA WITH JEQUIRITY.

After referring to the failure of the various plans of treatment in this affection, he stated that in order to obtain the best results, it was necessary to fulfil the following conditions: first, cleanliness; second, rendering and keeping the Eustachian tube patulous; and third putting the naso-pharynx into a healthy state. This last point is frequently entirely ignored. The mucous membrane of the cavity of the tympanum frequently passes into such a condition that it can only be relieved by changing it into cicatrical tissue; a condition similar to that found in tracheomatous inflammation of the conjunctiva.

This latter affection has recently been treated by inducing a violent inflammation by means of the infusion of jequirity. For the past year or two Dr. Seely has been treating certain cases of long-standing suppurative otitis media, by inducing inflammation with the solution of jequirity which has been used in the treatment of similar diseases of the eye, and he considers this plan of treatment of value under certain conditions, which he formulated as follows: 1, where there is extensive destruction of the membrana tympani; 2, where there is a great amount of thickening of the mucous membrane, thus rendering other plans of treatment futile or tedious; and 3, where there is a patulous Eustachian tube, a condition for regulating the inflammation.

Dr. J. J. B. Vermyne, of New Bedford, Mass., read the next paper, which was entitled

DISEASE OF THE ETHMOID, THE CONSEQUENCE OF CHRONIC CATARRH OF THE NASO-PHARYNX—EXOPHTHALMOS,

in which was described the case of a young lady of sixteen, who consulted the author on account of a slight protrusion of the right eye. The protrusion was forward and downward and had existed for some time. The eyelids were not œdematous. There was no dilatation of the veins, the conjunctivæ were normal and pain was absent. Ophthalmoscopic examination showed that the optic disk was slightly elevated and that the vessels of the retina were distended. There was slight hypermetropia on the right side, but vision was normal on both sides. Headache had been noticed for a few days before she came under observation. The general health was good with the exception of a chronic naso-pharyngeal catarrh, which had existed for eleven years and which had followed a severe attack of scarlet fever. This was particularly marked on the right side. The movements of the right eyeball were not interferred with. There was slight diplopia on awakening in the morning, but this continued only for a short time. A neoplasm in or around the nerve was suspected and the treatment directed accordingly. In a short time the patient entirely recovered with the exception of the protrusion of the eye. A further consideration of the case led the author to think that possibly the symptoms might be explained on another supposition than that of a neoplasm. A careful examination was again made, and a hard immovable nodular tumor, extending from the upper internal corner of the eye to the internal canthus, and which evidently was connected with or originated from the os planum, was found. The symptoms were then referred to the naso-pharyngeal catarrh and suitable treatment instituted. The case was considered to be one of retention tumor, similar to one which was reported by Dr. Knapp, in 1876, to the International Ophthalmological Congress. This opinion was largely based upon the fact that there had been frequently observed a peculiar appearance of the eye, which was compared to a lobster eye. The speaker referred to the fact that Dr. Knapp's case had been successfully operated on by the chisel: a plan of treatment which Dr. Knapp had advised in all cases of this kind whether of exostosis or of retention tumors. Another case of Dr. Knapp's, reported in the April number of the *Archives of Otology*, was referred to. The above operation was performed, but the patient died from traumatic meningitis. Disease of the osseous walls of the frontal sinus was found after death. In reviewing the conclusions drawn by Dr. Knapp from the last case, the speaker though it proper to ask what constitutes a comparatively healthy pneumatic, and whether some participation of the bone in the neighborhood of the tumor can not with reason be suspected? And also, considering the lesser danger which might attend simple mechanical distention of the bone, whether an explorative puncture with a trocar would not become imperative, instead of being unnecessary, as stated by Dr. Knapp, and whether in tumors of this kind, when not endangering the eye and not of inconvenient size, it would not be better to let them alone as has been advised by other authorities?

Dr. Vermyne also read a paper on

MYXOFIBROMA AT THE BASIS CRANII, CAUSING BLINDNESS, AND SEVEN YEARS LATER, COMPLETE DEAFNESS BY DESTRUCTION OF THE LABYRINTH.

The patient was first seen in the early part of 1876, dimness of vision and fatigue of the eye being complained of. Vision $= \frac{12}{xx}$. There was slight congestion of the optic disk and of the retinal vessels. Three months later, severe headache and optic neuritis appeared. Under the use of the artificial leech and the administration of large doses of bromide and iodide of potassium

the patient improved. The patient passed from under observation on account of the statement to the patient's parents that there was probably a cerebral tumor, and that the improvement was likely to be only temporary.

Five years later the patient was again seen, and secondary atrophy of both optic disks was found. In 1873 she became deaf; but six weeks' later she could hear almost as well as before. After this the hearing gradually disappeared. The patient died in May, 1874, eight and a-half years after the first observation.

At the autopsy, a tumor measuring six centimetres in length, four centimetres in width, and two centimetres in thickness was found occupying the left inferior occipital fossa. The left half of the cerebellum had been compressed to one-third of its normal size. The consistence of the cerebellum was increased, and both it and the cerebrum were anæmic. A considerable amount of fluid was found in the ventricles. The tumor in its growth had impinged upon the petrous portion of the temporal bone of the left side, and had caused the entire destruction of that portion of it between the posterior wall and the tympanic cavity, which had been opened.

The speaker considered that the first symptoms of the tumor were those referred to the eye; that in all probability the tumor originated from the dura mater, and that the effect upon sight and hearing was to be attributed entirely to interference with the circulation from mechanical pressure.

Dr. Charles Kipp reported two cases of a similar nature, in one of which the frontal sinus, the ethmoidal cells, and the sphenoidal cells, were filled with innumerable polypi.

A CASE OF EPITHELIOMA OF THE AURICLE

was reported by Dr. Charles J. Kipp, of Newark. The growth developed in a young man aged nineteen, and had been growing for one year. It involved the concha and closely resembled a mass of granulation tissue, but it was harder than this, and this condition led to the diagnosis of granuloma. It was removed, the wound healed, and the case passed from under observation, so that its subsequent history could not be obtained. The microscope showed the growth to be made up to a great extent of epithelial cylinders, imbedded in a very vascular, fine fibrillar tissue.

Dr. Kipp also exhibited a cavernous fibro-liponia which he had removed by excision from the auricle of a man thirty-one years of age.

Dr. L. Howe read a paper entitled

HÆMATOMA AURIS—ITS TREATMENT WITH ERGOT.

The condition had occurred in a sane woman aged twenty-eight, without apparent cause. Hypodermic injections of ergot were tried with the effect of greatly diminishing the size of the auricle.

Dr. Samuel Sexton read a paper on

THE INFLUENCE OF DENTAL IRRITATION ON THE EAR.

A number of plaster casts were exhibited, showing the condition of the teeth in cases in which the ear symptoms were found to be due to the caries or other trouble with the teeth, and in which relief was only obtained when these difficulties were corrected.

The following papers were read by title: Dr. Todd's, of St. Louis, Mo., entitled, "Necrosis of the Right Labyrinth; Total Facial Paralysis on the same Side; Partial Recovery;" Dr. Burnett's, of Philadelphia, Pa., on "Reflex Aural Phenomena from Naso-Pharyngeal Catarrh; Objective Noises in and from the Ear;" and Dr. H. N. Spencer's, entitled, "A Simple Device for the Treatment of Nasal and Post-nasal Inflammations, and on the Importance which Attaches to such Conditions of Inflammation as they are Related to the Ear."

Professor F. E. Clarke read a paper in which he asked for a reliable test for hearing, by which the difference between hearing and feeling might be determined; for a method by which the hearing might be developed or improved, and whether injury might be done in these cases by loud noises, etc.

The paper was referred to a committee of three, of which the President of the Society was to be chairman.

The Society then went into executive session.

The new members elected were: Dr. E. D. Spear, Jr., Boston; Dr. John Vanduyn, Syracuse, and Dr. S. O. Richey, Washington.

OFFICERS FOR THE ENSUING YEAR.

President—Dr. C. H. Burnett, Philadelphia; *Vice-President*—Dr. J. S. Prout, Brooklyn; *Secretary and Treasurer*—Dr. J. J. B. Vermyne, New Bedford, Mass.; *Committee on Publication*—Dr. J. J. B. Vermyne, Dr. C. J. Blake, Dr. O. J. Green; *Committee on Membership*—Dr. John Green, Dr. H. G. Muller, Dr. H. O. Moyes.

The next meeting to be held at the same place as the American Ophthalmological, and on the day preceding its meeting.

The Society then adjourned.

THE PARIS ACADEMY OF MEDICINE.

Stated Meeting, June 24, 1884.

M. Alphonse Guérin, President, in the Chair.

(Special Report for The Medical Record.)

The Academy having been called to order, M. Fauvel, at the request of several of the members, made a short report upon

THE CHOLERA IN TOULON.

He had already had occasion, before the Consulting Committee on Hygiene of France, to express the opinion which he held that the present epidemic was not Asiatic cholera. All the facts in connection with the case go to prove that the disease is of local origin, and is due to the herding together of a considerable number of troops placed under defective hygienic conditions. These same conditions have before now, notably in England, caused outbreaks of epidemics, attended with great mortality. Such epidemics are ephemeral, continuing and subsiding along with the conditions which have given occasion to them. The mode of origin of the epidemic in Toulon, and its subsequent course, have nothing in common with our ideas of Asiatic cholera. Whenever this dreaded disease visits a large community, it strikes with great fury and advances with extreme rapidity, so that it reaches its maximum of intensity within a few days, having then attacked all those who are susceptible to its influence.

M. J. Guérin asked that M. Fauvel might be a little more explicit in his report, so that the Academy might not be dependent upon the daily papers for information concerning the Toulon epidemic.

M. Fauvel regretted that he would not be able to give any more detailed information until the next meeting. He could state, however, positively, that the epidemic was declining.

M. Bouley announced that MM. Roux and Straus had left for Toulon, and would bring back some valuable documents bearing upon the origin and nature of the disease there prevailing. These documents would be laid before the Academy when the question of the cholera epidemic came up for discussion.

M. Bucquoy then related a case of

FARCY,

occurring in a coachman, nineteen years of age. The patient, who had been ill for a fortnight, presented all the symptoms of typhoid fever, except that there were no rose-colored spots nor any gurgling on pressure in the right iliac fossa. A little later, M. Bucquoy noticed a small round ulcer on the external surface of the right leg, and an abscess a little higher up on the limb. With-

in a short time the patient had a severe chill, and this was followed by swelling and redness about the right ankle. Suppuration soon appeared within the joint. Several of the other articulations became similarly affected, the patient rapidly lost strength, and finally died. Just before death the body was nearly covered with an eruption of bullæ. The author inoculated an ass with fluid taken from the body of this patient, and the animal sickened with farcy, thus showing conclusively the nature of the disease from which the young man had suffered. It was ascertained afterward that the patient had slept in a stable in which was a horse affected with glanders.

A communication to the Academy from Madame Paquereau, regarding the interests of

MIDWIVES IN ALGERIA,

was then reported upon by M. DE VILLIERS. He declared himself in favor of recognizing the midwives practising in that colony.

The Academy then adjourned.

THE BIOLOGICAL SOCIETY OF PARIS.

Stated Meeting, June 21, 1884.

M. PAUL BERT, PRESIDENT, IN THE CHAIR.

[Special Report for THE MEDICAL RECORD.]

THE Society having been called to order by the President, M. BOCHEFONTAINE read a communication on the

ACTION OF SALICYLIC ACID UPON RESPIRATION.

He had observed the effects of the drug upon healthy individuals and those suffering from typhoid fever. The respiratory movements became more regular under its influence, probably by reason of its action upon the medulla oblongata.

M. DÉJERINE had recently been studying the

PERIPHERAL NERVE-LESIONS IN LOCOMOTOR ATAXIA,

and presented a report of his investigations to the Society. The man, a patient in M. Vulpian's service, had a sclerosis of the posterior and lateral columns. There was complete anæsthesia of both lower extremities, with the exception of a small area on the inner surface of the right knee, where sensation was preserved. M. Déjerine found marked changes in all the peripheral nerves except those supplying the area of preserved sensation. The lesions were less marked in the cord than in the nerves. The author insisted upon the importance of this localized neuritis in the symptomatology of ataxia.

M. DUMONTPALLIER related a case of

INDUCED BILATERAL HALLUCINATIONS.

The subject was an hysterical female who had been hypnotized. While in the somnambulistic state, a card was placed perpendicularly between the eyes so as to divide the field of vision into two parts. A pleasant image being presented to one eye and a disagreeable one to the other, the impressions thus conveyed to the hemispheres were reflected back to the corresponding halves of the patient's countenance. These impressions persisted even after the patient was awakened, the two sides of the face expressing the opposite sentiments of joy and grief. M. Dumontpallier believed that he was the first to produce these suggestions to the brain by influencing the retina alone.

M. GLEY had endeavored to repeat the experiments of M. Aphanasieff in the

TRANSFUSION OF PEPTONIZED BLOOD.

He had at first made use of peptones of German manufacture, but had found them too impure for this purpose. He had, however, succeeded in arresting coagulation by means of a liquid obtained by the washing and maceration of a pig's stomach.

M. BEAUREGARD described the

HEART OF THE SPERMACETI WHALE,

which he had recently had an opportunity to examine. It measured nearly three feet in length by a foot and a half in width, and was of an oval shape. The right auriculo-ventricular valve had three segments, the left had four. The sigmoid valves were without any nodules. The bone of the heart was absent. The heart of the spermaceti whale would thus appear to be intermediate between that of the ordinary whale (balæna) and the dolphin. Another point worthy of mention was that the walls of the left heart were no thicker than those of the right.

M. P. BERT remarked, regarding the equality in thickness in the walls of the two sides of the heart, that this was as it should be physiologically, since in the whale the blood was to be propelled horizontally and not upward. One could easily understand that it would require a stronger heart to pump the blood upward into the head of a giraffe than forward into a whale's head.

M. OKOROVITZ then read a note upon

IDEOPLASTY,

or the physiological realization of ideas.

This was followed by some further remarks by M. BERT upon

ANÆSTHESIA FROM DILUTED CHLOROFORM VAPOR.

He agreed with M. Aubean, who had read a communication upon the same subject at the preceding meeting of the Society, that the best mixture was one of eight parts of chloroform to a hundred parts of air. This mixture caused death in a dog in three hours; but if the strength was reduced to six per cent. the fatal termination was delayed for nearly seven hours. Although man bears chloroform better than the dog, M. Bert thought it advisible, nevertheless, after anæsthesia had been produced by the eight per cent. mixture, to reduce the strength somewhat. The author stated further that when an animal had once fallen into the most profound anæsthesia, it would absorb no more chloroform until the anæsthesia had begun to diminish.

M. BROWN-SÉQUARD related a case of

CHLOROFORM NARCOSIS MAINTAINED FOR EIGHT DAYS.

The patient was an epileptic who had sustained a fracture of the arm, and it was consequently of paramount importance to prevent the convulsions for a time. Two of his assistants, medical men, were his authority for the assertion that the sleep had not been interrupted during the whole of this time. Simpson has recorded two cases in which chloroform narcosis was prolonged for three days.

After the election of a new member the Society adjourned.

MR. GAMGEE'S SPONGE.—Mr. Sampson Gamgee has recently shown his new absorbent sponge before the Société de Chirurgie. The description of it is as follows: "A small capsule, containing eucalyptus or other antiseptic, was enclosed in absorbent cotton; outside of this was a layer of cocoanut fibre, and outside of this more absorbent cotton-wool; the whole being enclosed in gauze. When about to be used the capsule could be broken by a blow of the fist, and the absorbent cotton become permeated with the antiseptic. He said these sponges could be made at a very trifling cost, and hoped they would come into use as a cheap substitute for ordinary sponges; they possessed this great advantage, that when required for use they were certain—however long they might have been kept—to be antiseptic: and, being so cheap, they might always be destroyed after being used."

Correspondence.

THE QUESTION OF THE FLORIDA CLIMATE.

To the Editor of The Medical Record.

Sir: The number of phthisical cases visiting Florida during the winter of 1883–84, physicians and landlords assured the writer during a stay of some months there, was greater than ever before. Gainesville may have been an exception, but certainly not if scarcity of suitable food and accommodations are a criterion. Approaching Gainesville from the direction of Palatka the country is almost an unbroken level, as it is in leaving Gainesville and proceeding toward the Gulf coast; this topographical characteristic has probably been observed by thousands who have visited Gainesville, as well as myself. There is therefore no natural fall nor inclination of streams toward any great river nor the Gulf of Mexico, no basis for natural drainage. The construction of artificial drains would, owing to the level surface, involve great expense. The Alachua Sink, a few miles distant, would from a sanitary standpoint be considered rather as a source from which the germs of malarial disease might be disseminated during the spring and autumn months, than otherwise. Practically, the throat leading to it is choked up with débris and the surrounding country overflowed by a vast and virtually stagnant pool of fresh water, into which the element of vegetable decomposition must of necessity enter, aided by absence of outlet and the flat configuration of the land. The calcareous deposits and in places marshy soil account for the inferior quality of the drinking-water in those parts.

With reference to the large number of deaths, a clergyman well known and high in the church, one who has spent many winters in Florida, and one certainly not likely to make such an assertion unless founded upon the flinty rock of fact, affirms that during his visit in Gainesville deaths from phthisis occurred nearly every day or two, and that cadavers were frequently removed by night from the hotels by the back door, in order that depressing influences might not be exerted upon patients, non-phthisical or otherwise. Darkness cannot conceal the cold white face, and the little world in the "Land of Flowers" knows that another is gone to his or her long home.

One word about Cedar Key, or Cedar Keys as it is written in not a few books and maps and so called by inhabitants. During a sojourn there the prettiness of the little place, with its row of bearing orange-trees on either side of the street, impressed itself upon my mind. There is a certain balminess in the air not noticeable on the Atlantic side. The approaches are perfectly flat, and there is no obstruction to the mild zephyrs coming over the placid waters of the Gulf or across the numerous little keys studded with palms and cedars. It is a typical spot to which Tampa, although much farther south, bears some resemblance, and if phthisical cases ought to be sent to Florida at all, which is extremely doubtful, they would certainly derive more benefit anywhere on the western coast than along the borders of the Atlantic Ocean. There is naturally considerable jealousy between rival towns eager to secure the greatest number of visitors, and doctors differ as widely in their views about Florida as a health resort as about anything else. Opinions founded logically upon reason and individual observation are not likely to be changed, and further argument upon the subject would not only be futile but would also be trespassing idly upon the valuable pages of The Medical Record. Yours very truly,

G. Halsted Boyland, M.D.

July 2, 1884.

The White of an Egg must no longer be looked upon as a simple albuminous body. Leboute, Goumoens, Scherer, and recently Dr. E. T. Reichert have found that there exists in it a globulin and a peptone.

THE ABUSE OF MEDICAL CHARITY IN THE SOUTH.[1]

To the Editor of The Medical Record.

Sir: I desire to direct your attention to the evils of charity practice as conducted in our city, and in fact not only in Knoxville, but also throughout the country at large, wishing to place myself on record as opposed to the present custom. I will also endeavor, with a few brief remarks, to suggest a more satisfactory mode of practice, both to the practitioner and to the *worthy* poor.

I take it, we all, every one of us, are practising our profession for our bread and butter, however much we may speak of the honor and glory attendant upon the practice of our truly progressive science. When we are called to a patient we expect and certainly ought to receive compensation for our services, and yet how many are there among us who have not scores upon scores of pauper patients upon their account books, and who is there among us who does not go, always go, time after time, to the same pauper patients, knowing beforehand that we will never receive any pay for our services? I am speaking now of pauper patients as a whole, including all classes — all who are recipients of gratuitous practice. It is a thankless practice, whether we treat a miserable dead-beat or a deserving pauper. To the busy practitioner the attendance on the pauper class directly takes money from his pocket, consuming valuable time, time which could otherwise be given to the better classes of his clientele. As it now is, the busy active doctor will often attend before, and give more attention to a poor patient than to a well-to-do patient, for the simple reason that he is afraid it will hurt his reputation if he fails to find time to wait upon the poor who call upon him. He is afraid some one will say, "Oh! Dr. So-and-so will not call and see me because I am poor." He does not attend the poor from a feeling of duty, for honor, glory, or fame, but simply out of policy. Policy is a fine scheme. Leave policy out of consideration, and I think a number of reputed benevolent, warm-hearted physicians would be shorn and bereft of their laurels. Mind, I do not say all. I only say a number. I know there are hundreds who are really deserving of their reputation for warm-heartedness, benevolence, and philanthropic measures; but after all is said and done, we are but human, we doctors, and we practise for dollars and cents.

Another feature is the character of treatment we render to the poor. And right here I will say I expect I will receive censure for saying that I think the majority of us neglect the poor. I do not think we are as careful and painstaking with them as we ought to be. While here and there we may find a conscientious practitioner, one who will give as much attention to a pauper as to first-class pay patients, I am free to say I do not believe that the majority of us give them the care and attention *we* ought and that *they* deserve. For I hold that no man, in any business whatever, not even the profession of medicine, will give without a *quid pro quo*, the same care, energy, thought, and attention that he would bestow for a consideration.

Perhaps before continuing further it would be well to make a division or separation into classes of those who are called charity patients. I divide them into simply two classes: first, dead-beats; second, the worthy poor. There is no need of further subdivision. These two classes include the whole mass of charity patients. Of the truly worthy and needy poor, I have this to say: it is the duty of every man, in whatever walk of life he may move, to help, relieve, and succor a poor, distressed, and afflicted brother, he being worthy. It is the bounden duty and becomes the solemn obligation of every village and county to take care of their worthy poor; but because it is right and just that the

[1] This letter is the substance of an address delivered before the Knox County Section of the East Tennessee Medical Society, May 29, 1884.

worthy poor should be taken care of, it is not right, nor is it just, that the care, labor, attention, and in many cases expenses also, necessary for their assistance and relief should be saddled upon a few only of the community, simply because they always have shouldered the burden and carried it, not only without compensation but without murmur or grumbling. To be sure, ours is a liberal profession (in more senses than one) and in all ages and all time we have ever been ready and willing to respond to the call of charity, not only with money itself but with the knowledge, skill, and understanding of treatment our professional attainments should be composed of. This is a very mistaken idea. This is all wrong. Because we have heretofore, do now, and probably will hereafter do these things is no reason why we should be imposed upon. A free horse should not be ridden to his death. Yet it is our own fault, all our own fault; the remedy lies in our own hands. We can stop this wrong system of practice if we only will do it.

I have talked with numbers of our profession, both here and elsewhere, and I have yet to find the first man who does not condemn and deplore the present system of practice, and yet all, not one exception, but express themselves as ready to attend the needy poor. To distinguish always between the worthy and unworthy poor is not easy. The dead-beats we all know (after we get through with them); those who run up a bill and employ you as long as they dare, and then apply to some one else, because, perhaps, they don't wish to lay themselves liable to be refused your services; perhaps because they are ashamed to call you in after they have made large bills. They are the ones who dodge you on the street corner, who would rather go squares around than pass your office or house. In this way they go the rounds, and every new doctor is sure to be overrun with these patients, who owe every doctor in the neighborhood, and in this way get their entire professional services free, as it takes them their lifetime to make the rounds of every physician in a city of this size. Some of them, it is true, die before they get clear around. Sad, is it not! Then, too, there is a singular peculiarity about these miserable dead-beats; it is this, they more frequently call you out at night for trifling ailments. If a farmer living in the country, he cannot spare a horse or man from the field to send after you in the day-time, but must needs wait until night, after the day's work is done, and thus entail double duty on man and beast, for he never goes himself, but sends a neighbor.

There is another important feature with this class of practice: nine-tenths of all the suits for malpractice one has or may hear of, if one takes the trouble to look them up, will be found to have been instituted by some miserable scoundrel of a dead-beat. You find them all alike. They are the men who find it cheaper to move than to pay rent, and as they move back and forth through the city leave their bills at drug stores, at the grocer's and at the butcher's unpaid. You recognize the man. You all know him. These are plain, unvarnished truths.

Perhaps I have drawn out and spread over too much paper my conception of the evils of the present system of charity practice. In treating of the remedy, which I claim lies in our own hands, I will try and be more brief, and at the same time give a clear outline of what I conceive to be the best way out of the dilemma. Let me preface by saying that, did this problem lie before any other class of men than physicians it would be quickly and readily solved. But physicians are proverbially unbusinesslike. As one of the first steps toward reform in this direction let us make out, and keep up and compare full and complete black-lists, not merely talk of it and once in several years exchange a hasty memoranda of delinquents, but regularly every quarter, say, revise the old black-lists carefully and make such additions and alterations as is necessary, bring your new list to your medical society, each man hand his list to the secretary, and have the secretary make out a complete list and furnish one to each member of the society, have them in printed form if desired. By doing this in earnest, not making a farce of it, we will accomplish a great deal. We will create more of an interest in our society. We will bind ourselves more closely together, and will naturally work more harmoniously together, and be in better shape to secure the accomplishment of our desires whatever they may be.

We should not only have *one* city physician, but *we all* should be *city physicians*, and receive pay in proportion to the amount of work we do. Another thing, in regard to the city hospital. Under the present regime the hospital practice is in the hands of a select few. If any outsider has an interesting case, which of a necessity is obliged to avail himself of hospital privileges and accommodations, he is obliged to turn over his patient to the select few. In Stillwater, Minn., a city of fifteen thousand population, where I practised some little time before removing to Knoxville, *any* physician in the city was privileged to take a patient to the city hospital and wait upon him himself. The system worked well, and is in vogue to-day in Stillwater, giving excellent satisfaction.

In several parts of the old country, in Germany, which I recall in particular, where an individual is sick, or members of his family are sick and need professional care and is unable to pay for same, he makes application to one of the town officials for aid. The official gives him an order to a physician (the applicant selecting his physician) to wait upon him, and also gives him an order to the apothecary for necessary medicines, which order must be countersigned by the physician. Then the physician and apothecary present their orders to the treasurer or proper official and are paid their bills. A certain schedule of prices being authorized by law at a certain per cent. discount from the regular fee-bill.

In some parts of Michigan, also in Lancaster, O., a similar law prevails. Other places that have this system I cannot now recall. In our own city, perhaps, the best way is, when a pauper requires medical attention let him apply to the alderman of his ward—aldermen are usually pretty well acquainted with the people of their wards (at least immediately preceding a municipal election)—and let the alderman be empowered to give an order to any physician the applicant prefers; at the same time giving an order to the apothecary for the necessary medicines, this order to be countersigned by the physician to be of any value.

If this work is considered by the aldermen as derogatory to their official dignity and position as city fathers, let the proper power be conveyed to the assessor and his deputies. If their duty is already too arduous, let there be constituted an additional Board of Poor Commissioners, one or more to each ward, with a nominal salary. But to whosoever this power be relegated, make it obligatory upon them to personally familiarize themselves, either before or immediately after giving the order, with the worldly condition and financial standing of the applicant in order to guard against imposture, and also make it obligatory upon them to keep a full record of all orders drawn, giving name of applicant and members of family, his and their occupation, and the amount of money earned by the family; by this means ascertaining whether they are worthy recipients of charity or not. Let them also keep a record of the date of application, and names of physician and apothecary whom orders are drawn upon. Make it also a duty of the physician to render a full report of each case to the Board of Poor Commissioners, all proper blanks being furnished by the city. Then let us physicians adopt a charity fee-bill; either a new one designed for this class of practice or make a certain per cent. discount from our regular fee-bill.

These are my ideas on the evils of charity practice and of the proper course of treatment indicated. If this treat-

ment is adopted and adhered to, I think the prognosis extremely favorable. But the profession must be united in its endeavors. In union there is strength. United we will make a success of it; divided we will ignominiously fail.

T. W. SHEARDOWN, M.D.

KNOXVILLE, TENN., May 29, 1884.

MORPHOLOGICAL STATUS OF THE CEREBELLUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with considerable interest the elaborate lectures[1] delivered under the provisions of the Cartwright bequest by Professor Wilder. Having given attention to the matters with which that distinguished anatomist deals, permit me to offer some suggestions regarding a single proposition made by him which cannot, I think, be sustained. The lecturer follows the lead of a number of comparative anatomists in regarding the cerebellum as a distinct segment of the primitive group, under the name of *metencephalon*. He goes further than they in creating, as it were, a new ventricular subdivision, in order to render this classification consistent. This is the anterior portion of what all authorities have agreed in regarding as the fourth ventricle, according to Wilder the *epicœlia*.

Practically we all recognize that the cerebellum is an important segment of the adult brain; indeed, the classification of the parts of the adult brain, useful for medical students and for the localizationalist, can scarcely be made to correspond to morphological or embryological requirements.[2] I need but refer to the case of the thalamus, which is an outgrowth of the embryonic *thalamencephalon*,[3] and really one of the finest representatives of an embryonic segment which could be cited. In man and higher animals, however, so intimate has become its secondary fusion with the medullary centre of the hemispheres, that it assumes the position of an intracerebral ganglion, comparable to the lenticular nucleus and the caudate mass of the corpus striatum. So absolute is the dominion of the cerebral hemisphere over the thalamus, that the ventricular cavity of the former, in man and apes at least, encroaches on the dorsum of the thalamus a short distance beyond the caudo-thalamic groove, as if to falsify the embryonic relations of the derivative cerebral vesicle to its parent thalamic vesicle. I cite this case to show that the embryonic importance of a segment is not a proper gauge of its importance to the physiologist and physician and that therefore conversely the importance of a segment—like the cerebellum—to the physiologist and physician is not an indication that it occupies a correspondingly important place in the embryologist's calculations. To a certain extent the aims of morphological and physiological anatomy are distinct. To the comparative anatomist the pituitary body and pineal gland are of much more fundamental importance than the pyramid tract, while the physiologist discards the former and attaches the greatest value to an accurate knowledge of the latter, just as the surgeon is more interested in understanding the mechanism of the atlanto-occipital articulation than in being told by the morphologist that the *ligamentum suspensorium denti epistrophei* contains a notochordal relic. I say this with a full appreciation of the high biological importance of even unpractical facts, which, if I could attest in no other way, I needed but to refer to a few original discoveries which I have been fortunate enough to stumble across while undertaking researches in this field.

The reasons why I cannot agree in regarding the cerebellum as a primary segment, nor the *epicœlia* as a primary ventricular subdivision, are the following:

1. Primarily, the cerebellum is only the dorsal part of the wall surrounding the anterior part of the cavity of the hind brain (fourth ventricle).

2. The ventral part of this wall is morphologically continuous with and inseparable from the posterior "open" part[1] of the fourth ventricle.

3. The cephalic portion of the fourth ventricle is distinguished from the caudal portion only by the fact that in the former the roof—and the roof alone—undergoes hypertrophy, while in the latter it—and it alone—undergoes atrophy. If this fact is to constitute a discrimination between two cerebral segments, then the closed portion of the oblongata should be separated from the open portion.

4. There is at no time an indication of a boundary (of the kind found with other ventricular cavities in all higher forms) between the *epicœlia* and *metacœlia*. The *procœlia* are separated from the *diacœlia* by a constriction, the *porta Monroi*; the *diacœlia* and fourth ventricle are demarcated from the *mesocœlia* by a sudden narrowing,[2] but where is the boundary between the two divisions which Wilder makes of our old familiar fourth ventricle? It happens to widen out at the (imaginary) boundary.

5. Dr. Wilder recognizes the necessity of finding a ventral part of his epencephalic segment, and believes to have found it in the pons. The term "pons" in one sense indicates an arbitrary division; in another it is used to designate only the (apparently) transverse fibre mass which is thrown across the brain-axis like a belt. This is not a commissural mass, however. Nearly all its fibres pass to the crura cerebri, either with or without ganglionic intervention, according to the testimony of Gratiolet, Meynert, Vernicke, and Flechsig. Morphologically they are heralded in lower animals by arciform fibres which are continuations of the zonal fibre system common to the entire myelencephalon of reptiles and birds. There is hence no support to be derived from the existence of this apparent basilar commissure for Wilder's designation. This objection is strengthened by the next.

6. There is not even an approximate uniformity in the boundary of the *epencephalon*. If the extent of the cerebellum be taken as the gauge, it is almost *nil* in *menobronchus* and extremely large in man. Homologous parts of the ventricular floor fall within the *epicœlia* in man and without in reptiles. If the extent of the pons be taken as a guide, then this segment is absent in reptiles and birds, it is a narrow belt in the opossum, twice as wide in the rabbit, thrice as great in the dog, five times as great in the ape, and six times as wide (cephalo-caudad) in man.

The only indication of a cœlian monopoly on the part of the cerebellum is the tent-like projection of the fourth ventricle into the *fastigium*. Indeed, in birds—like the ostrich—it is a closed pond, communicating with the fourth ventricle by a narrow slit. But this is not a ventricular *segment*, but a *diverticulum*, like the primitive cavity of the *hypophysis* (pituitary body) or the *conarium* (*epiphysis* or pineal gland). I think this comparison suggests the true morphological *status* of the cerebellum.

Respectfully,

E. C. SPITZKA.

TREATMENT OF PHLYCTENULAR OPHTHALMIA.—Dr. H. Power recommends as a local remedy in cases of phlyctenular ophthalmia an ointment commonly called Pagenstecher's, which is a combination of vaseline with binoxide of mercury, in proportions varying from one to ten, or even fifteen, grains to the ounce. This forms a yellow ointment, which in the milder forms gives scarcely any pain, but in the stronger proves sharply irritating to the eye, inducing free lachrymation. Dr. Power thinks that this preparation may be regarded as a specific for corneal ulcers.—*Louisville Medical News.*

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 13 to July 19, 1884.

WRIGHT, J. P., Major and Surgeon. Assigned to duty as Post Surgeon, San Antonio, Texas. S. O. 87, par. 4, Headquarters Department of Texas, July 14, 1884.

MCELDERRY, HENRY, Captain and Assistant Surgeon. From Department of the Platte to Department of the East. S. O. 165, par. 12, A. G. O., July 16, 1884.

EWEN, CLARENCE, Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Sidney, Nebraska. S. O. 58, par. 8, Headquarters Department of Platte, July 11, 1884.

ELBREY, F. W., Captain and Assistant Surgeon. Leave of absence still further extended six months on surgeon's certificate of disability. S. O. 161, par. 6, A. G. O., July 12, 1884.

WAKEMAN, WM. J., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort D. A. Russell, Wyo., and assigned to duty as Post Surgeon, Fort Washakie, Wyo., relieving Assistant Surgeon Norton Strong. S. O. 58, par. 9, Headquarters Department of Platte, July 11, 1884.

EWING, CHARLES B., appointed to be Assistant Surgeon, with the rank of First Lieutenant, July 5, 1884, *vice* Middleton, promoted. Memorandum, A. G. O., July 14, 1884.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 19, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
July 12, 1884	2	8	55	4	187	31	0	0
July 19, 1884	3	15	50	3	167	27	1	0
Deaths.								
July 12, 1884	0	3	14	3	27	18	0	0
July 19, 1884	1	5	11	3	30	16	0	0

THE AMORPHOUS BORATE OF QUININE is a preparation highly recommended by Finkler and Prior, who have used it in the clinic at Bonn. Its advantages are that it does not irritate the stomach, and that it has a more powerful antiseptic action in the digestive tube. It is used in about the same doses as the sulphate.

CEREBRAL ANÉMIANTS AND HYPERÉMIANTS.—Curci, experimenting upon dogs by trepanning and attaching a uranometer, finds that chloral, chloroform, ether, paraldehyde, and quinine, produce cerebral anæmia; morphine and nitrite of amyl, hyperæmia. Atropine in small doses has little effect; in larger doses it is rather an anémiant.

CHLOROFORM IN THE TREATMENT OF TAPE-WORM.—Dr. J. G. Brooks writes to the *Medical and Surgical Reporter*: "I have had within the last three years several cases of tape-worm to treat, and, finding such strong objection to the large draught of medicines in ordinary use, I prescribed the following: ℞. Chloroform, ex. male fern, āā f℥ j.; emul. ol. ricini (50 per cent.), f℥ iij. M. Sig.—All to be taken at once after twenty-four hours' fast. In every case the medicine was well borne, and the worm expelled entire. In two cases I omitted the male fern, and the result was the same as when the latter drug was in combination. My object in reporting this treatment is to induce others of the profession to try the chloroform and report results. I claim for this agent a specific and rational action as an adjuvant in the expulsion of the worm. It anæsthetizes or suspends vitality, and any active purge during anæsthesia of the tænia is all that is requisite to expel it. I earnestly ask those who have cases to try the chloroform, or chloroform and male fern, as above prescribed, and report results."

IN THE TREATMENT OF SPRAINS, Dr. Brinton, in the *College and Clinical Record*, recommends that the limb is to be put into a vessel of very hot water immediately, boiling water being added as it can be borne, and kept immersed for twenty minutes, or until the pain ceases. Then put on a pretty tight bandage and order rest. Sometimes the joint can be used in twelve hours. If the trouble is more chronic, apply a silicate of sodium dressing, and let the patient walk with a cane, if the ankle be the joint affected.

THE QUESTION OF THE FEEDING OF INFANTS has been recently discussed in the *British Medical Journal* by Drs. Beatty and Davies. The latter gentleman gives the following presentation of his view of the matter. He says: "Now, as the food we are at variance about is milk in its usual state from the cow, or condensed, let us see how we stand. Dr. Beatty recommends one part of milk to three of water, I recommend two parts of milk to one of water. Now let us take the composition of milk, and then judge as to which approximates nearest in strength to the mother's.

	Woman.	Cow.	Ass.
Casein (cheesy matter) and insoluble salts	3.35	4.55	1.70
Fatty matter	3.34	3.70	1.40
Sugar of milk and soluble salts	3.77	5.35	6.40
Water	89.54	86.40	90.50
	100.00	100.00	100.00

From this analysis it will be seen at once that Dr. Beatty's is much too weak. It is estimated that a healthy woman gives three pints of milk in the twenty-four hours; therefore an infant should have at least a quart of cow's milk a day, as much must of necessity be wasted by giving it by the bottle, and I know of no reason, nor have I ever read of any, which shows that a woman's milk is weaker at first than it is in four or five months after parturition. Now, with regard to condensed milk, 'the First Swiss Brand,' that is, the unsweetened milk (the only kind that should be used), is four times as strong as ordinary milk from the cow; therefore, a tin would be equivalent to a quart of milk. I say a tin a day is about what should be given, diluted with five times its bulk of water. Dr. Beatty says he orders a teaspoonful (!) to a quarter of a pint of water, at first, and says infants thrive on it; that may be his experience, I regret to say it is not mine."

SODIUM IODIDE INSTEAD OF POTASSIUM IODIDE.—Dr. Jno. D. Mulhane, of Steubenville, O., writes, refering to the article on "Sodium Iodide," of Dr. Berg (MEDICAL RECORD, vol. xxv., p. 542): "During the past year, while physician to Gould's Tunnel Panhandle Railway, I had under my care four hundred men, white and colored. In this class of fellows you find syphilis in all its forms. At first I used potassium iodide, but noticing that the late lamented Gross, in 'Surgery' (vol. i., p. 338, 1872) was very partial to sodium iodide, I used it in one hundred and seven cases, and in not one did it produce that dryness of air-passages which follows potassium when pushed. I heartily agree with Dr. Berg. No gastro-intestinal irritation in a single case."

ADDRESS ON PHYSIOLOGY,

DELIVERED AT THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION, JULY 29, 1884.

BY PETER REDFERN, M.D. LON., F.R.C.S.L.,

PROFESSOR OF ANATOMY AND PHYSIOLOGY IN QUEEN'S COLLEGE, BELFAST.

(Special for THE MEDICAL RECORD.)

Mr. President and Gentlemen of the British Medical Association: I value very much the honor of having been selected to give the address on physiology and I thank you warmly for the mark of your confidence which it implies.

The great problems of life have in all time had a profound influence upon the heart and mind of man. Whatever concerns the prolongation of life, or the increase of the capacity for enjoying it, the prevention or cure of those modified vital actions which we know as disease has always interested the mass of mankind. Hence the mission of medical men—as extensive as humanity, whatever form it takes—uninfluenced by age, or sex, or country—succoring alike the orphan, the criminal, the virtuous, the poor, and the rich. The medical man is the true friend of all within his reach; he advises, instructs, befriends all alike.

There is no one to whom accurate and incessant observation is so essential. His first step is to observe and record all the healthy phenomena of life; it is his constant care to secure the most fitting conditions for their exercise; and his last effort is to note how certainly their continued action brings about their own extinction, and how often they are suddenly arrested in their course by disease.

The delicate adjustments of vital operations and the unstable physical and chemical equilibrium of living structures present such difficulties to the physiologist that thousands of years of the world's history had passed before we had learned a single fundamental doctrine applicable to all life on the globe. Yet I doubt if as great progress has been made in any science as in physiology during the past fifty years, or if such an amount of labor has been expended in the same time on any subject as has been devoted to the study of physiology in the last quarter of a century. Still all we now know may appear very insignificant in the estimation of our successors of the next generation.

Every step in physiology concerns life and health; therefore each must be made as secure as possible. I think nothing has given as great confidence and security in the advance of physiology as the demonstration that all living matter has been derived from previously living matter of its own kind, and that all living beings and living tissues have originated from fragments of previously living beings or tissues, which, when detached, carried the properties of their parents with them.

It is quite true that living bodies are continually influenced and altered by external conditions; but it is also true that conditions at least as potent tend to their return to their original state. The changes which a particular mode of life may effect in the highest type of living beings may be such as to require three generations to make a glass-blower; but it is not probable that his children would care to preserve the advantages which they had derived by inheritance from their parent's father and grandfather.

The formed materials of our tissues differ widely from the original protoplasm to which they owe their origin; but some of that protoplasm remains in each, and still possesses powers of reproduction, which, in many instances, are no less startling because of the character than of the quantity of the tissue produced in a given time. The colossal increase in size, no less than the increase in number, of the muscular fibres of the uterus required to raise the standard weight of the adult organ from one and a half ounces to three pounds, is only paralleled by the still more rapid reduction in two or three weeks of the same organ from three pounds in weight to three ounces. This happens in an organ which is often more or less dormant for years together; but in the continually acting diaphragm, the presence of an unusual number of protoplasmic corpuscles in each fibre points to the greater and more persistent activity of the change which takes place there. Observe, in comparison with its cause, the vastness of the change produced in the mode of nutrition of the uterus, when an ovum only $\frac{1}{170}$th of an inch in size has come into contact with a still smaller spermatozoon; and the not less remarkable change when this ovum leaves the uterus. The establishment of different physiological relations has been attended in the first instance by deposition and formation of tissue; in the other, by its disintegration and removal.

Changes of external conditions produce as remarkable results. Mr. Ward found ill-fed plants of the common centaury (Erythræa Centaurium) only half an inch high, with one flower, at no great distance from better fed ones four or five feet high, covered with hundreds of flowers. Without other difference than greater looseness of the texture of the soil I had plants of the common rape (Brassica napus) between five and six feet high, freely branched everywhere, and carrying leaves as large as ordinary dishes, as contrasted with others close by, only fifteen inches high, but little branched, and having few linear leaves only about an inch long. And everyone is familiar with the marvellous change wrought upon the hive bee when, from being fed on royal jelly instead of an ordinary bee-bread, it becomes a queen. Yet these naked-eye evidences of the influence upon vital activity of a change in surrounding circumstances are insignificant in importance when compared with those of which the results are witnessed daily in medical practice.

Dr. Williams showed that when a drop of weak solution of capsicum is applied to the web of a frog's foot, dilatation of the arteries and capillaries takes place and more blood circulates through the spot in a given time than before, and that from this condition recovery may take place, and the experiment be repeated time after time on the same part. But if the solution be stronger recovery will not occur, and the increased rapidity of circulation will give place to slowing and stagnation. In the first instance the life of the vessels was affected and their contractility impaired transitorily, but the stronger solution destroyed their contractility more completely and produced the phenomena of inflammation, congestion, exudation, and stasis. No matter by what external means the life of the vessel is affected, the same result follows. And if the injury be inflicted from within by adding some irritant to the circulating fluid the effect is still the same.

Mr. Lister demonstrated, in a series of beautifully-contrived experiments, the delicacy of the relations between the walls of the blood-vessels and the circulating blood—that injury of the wall of a vessel causes arrest of the white corpuscles on the injured part, with coagulation of the blood; and if the injury be considerable, it will cause complete obstruction to the circulation. Disintegration of the white corpuscles takes place, and acts as an efficient cause of the coagulation and stoppage.

On the maintenance of this nice balance of the relations between the blood and the tissue over which it flows depends the issue whether the blood shall continue to flow or not.

The rupture of the internal coat of a vessel, or the alteration of the lining endothelium by endocarditis, causes arrest and disintegration of white corpuscles at the spot. Consequently, depositions of fibrin or the formation of thrombi on the valves of the heart are attendant phenomena on inflammation of the endocardium.

And Cohnheim found that stopping the circulation for from thirty-six to sixty hours, through particular vessels in a frog, and then allowing the circulation to go on again, was attended by such exudation as occurs in inflammation. The walls of the vessels had suffered injury from the temporary arrest of the circulation, their elements seemed to have been loosened, and exudation of certain of their contents took place.

It is important to note that this is not a mere passive transudation, it is attended with an active movement of the living corpuscles through the injured wall, a movement which does not happen in the instance of the mesentery to which solution of sodium chloride of double the normal strength, which stops the amœboid movements of these corpuscles out of the body, has been applied. An inflammatory exudation is readily distinguishable from the transudation of mere engorgement by being richer in albumen and corpuscles than it, and by coagulating more readily.

Dr. Burdon-Sanderson, in his admirable statement of the results of his own observations and in reviewing our present knowledge of inflammation, has called attention to the great accuracy of Sir William Bowman's early observations on keratitis, and has pointed out that not only do corpuscular elements migrate into injured spots of the cornea, but that they accumulate upon and within pieces of dead membrane or other tissue inserted into the peritoneal cavity. And Dr. J. Hamilton found that they so completely fill the cavities of pieces of prepared and engrafted sponge that it soon ceases to be visible. Dr. Sanderson has expressed the difficulty of maintaining that the migration of corpuscles is in such instances due to an increased attraction between them and the tissues, and he concludes that we are coming back to the notions of John Hunter, who accounted for the inflammatory blush by referring it to the action of the vessels.

On the other hand, it may be suggested that the changed conditions have diminished the restraining influence of the walls of the vessels and stimulated the corpuscles to more active migration than ordinary.

The interest and importance of the relations of the circulating fluids to the elements of the animal tissues demands a further consideration of them.

The structure and action of the supply vessels of any part are doubtless very important, but they can scarcely equal in importance the relations of the tissue and blood elements where these lie quietly in contact, and mutually influence each other.

One can scarcely exaggerate the importance of the observation that the pressure impelling the secreted fluid outward in a salivary duct is twice as great as that propelling the blood in the carotid artery, from which that gland is supplied, and that a large amount of secretion is discharged by a salivary gland, on stimulation of its nerve, after the circulation of blood has been altogether cut off from it. In like manner, at the instance of a nervous impulse, a muscle similarly withdrawn from the circulating current contracts and gives out carbonic acid and sarcolactic acid, neither of which was free in it before the contraction took place. And in the gastric glands, the pancreas, and possibly in all secreting glands, the constituents of the secretions are slowly abstracted from the blood and stored in some form of zymogen until a nervous impulse suddenly causes their transformation into the active principles of the secretion and its discharge.

Thus we localize the real laboratory of the organism—the place where the work of the body is done—the spot whence nervous impulses emanate—where motion results from chemical and vital changes—where the powers operate which regulate and produce secretions, excretions, nutrition, regeneration, and reproduction.

It will be admitted that the simplest mass of protoplasm, whether plant or animal, selects all it needs for the varied purposes of its life from the more or less fluid matters within its reach; and, in exactly the same way, the tissues of our bodies select what they need from the fluid plasma in which they are continually bathed. The vessels supply a larger or smaller quantity of this fluid as the demands of the tissues are greater or less at one time than at another; but it is the business of each tissue to select, both as to character and amount, all it requires, and in this selection, no less than in the use it makes of the materials it has selected, the tissue can only be very indirectly aided by the blood-vessels.

The anatomical relations of the tissue elements to the lymph spaces, by means of which they are continually bathed in lymph, are very interesting, and have been admirably described and illustrated by Dr. Klein in his "Anatomy of the Lymphatic System" and "Atlas of Histology." Dr. Curnow has given an excellent account of the history of the acquisition of our knowledge of the lymphatic system in the Gulstonian Lectures for 1879, published in *The Lancet*. Von Recklinghausen led the way, and so many accurate observers in different countries have followed him that we now stand on very safe ground.

The result has shown that the acini, or the tubes of glands, the bundles of fibres of tendons, the layers of the cornea, fasciculi of muscles, and funiculi of nerves, are in relation with lymph spaces, or vessels more or less completely lined by endothelial cells, and occupied by lymph containing amœboid corpuscles in variable numbers. These Dr. Klein has shown to belong to the same system as the spaces between the fibres and bundles of fibres of areolar tissue, which contain here and there flattened and branched endothelial or connective tissue cells folded over the bundles, which are themselves continually bathed in lymph containing amœboid corpuscles. Similar spaces under the mucous membrane of the alimentary canal or air-passages are continuous with the cement substance between the epithelial cells, where also branched connective-tissue cells occur, together with occasional amœboid corpuscles. All such spaces communicate directly with large lymph canals, immediately succeeded by irregularly dilated lymphatic vessels furnished with valves.

The immediate effect of medicines introduced endermically is abundant proof of the rapid and free communication of the lymph of the spaces of areolar tissue with the current of the blood, while, if Dr. Creighton's observations on the absorption of fat from the intestines be confirmed, we shall have learned that the emulsified fat of chyle passes through the cement spaces of the intestinal epithelium into the lacteal and mesenteric glands, the epithelium itself discharging the function of secretion.

But there are much larger reservoirs of lymph than the spaces of connective tissue, tendon, and cornea. The great lymphatic sac of the frog, the serous and synovial cavities, and the sheaths of tendons of mammals and man are similar spaces. Von Recklinghausen was the first to witness the passage of milk and other fluids contain-

ing visible particles through the stomata of the peritoneum covering the tendon of the diaphragm into the lymphatic vessels, and the disappearance of fluids from the peritoneal sac by this means. You will all call to mind many instances of rapid disappearance of recent pleuritic and peritoneal effusions; others, where such effusions have remained undiminished in amount for weeks and months, and some in which the effused fluid after a time assumed all the characters of pus. Coagulated blood does not disappear from the peritoneal cavity, but defibrinated blood is absorbed and its corpuscles continue to live in the circulating blood.

Ludwig and Schweigger-Seidel have pointed out that the respiratory movements are the chief cause of the entrance of fluids into the lymphatic spaces through the stomata of the peritoneum, and that during the descent of the diaphragm lymph is drawn into the spaces between the tendon bundles by their expansion, and pressed on at the same time in the pleural lymphatics furnished with valves, while during the ascent of the diaphragm, exactly the opposite action takes place, the diaphragm thus playing the part of a pump.

The pleura of the intercostal spaces is also provided with stomata and is similarly related to lymphatic vessels, and as there is an arrangement of a similar kind on the surfaces and in the substance of all fasciæ and tendon sheaths, it is not improbable that the connections of a large number of muscles with fasciæ rather than bones serves the same purpose. How much of the pleasure derived from muscular exertion depends upon the promotion of the circulation of lymph about all these parts, and upon their consequent invigoration, we may never be able to estimate, but no one can question the importance even in the limbs of a free circulation of lymph.

Let us now return to the contents of these spaces. We bear in mind that epithelial cells are masses of protoplasm variously modified for secretion, protection, or for entering into the construction of the terminal organs of the nerves of special sense, and that between epithelial cells, whether on the skin, the cornea, or on mucous membranes, there are spaces occupied by semi-fluid cement, with branched connective-tissue corpuscles, and amœboid or white blood-cells. We trace these cement spaces onward and find them continuous with the connective-tissue spaces under their respective membranes and with lymphatic vessels. In the different spaces the contained corpuscles vary greatly in number, but a food-supply is always afforded them by blood-vessels in proportion to their number.

Under extensive tracts of the mucous membrane of the alimentary canal and respiratory organs, very notably in the substance of villi and around Lieberkuhnian follicles in the intestine, the spaces are crowded with amœboid or lymph corpuscles forming adenoid tissue, or when masses of such tissue accumulate in more or less spherical or pear-shaped blocks they constitute solitary glands or the glands of the patches of Peyer. All such parts are supplied very freely with capillary blood-vessels, and as Brücke demonstrated many years ago, their spaces directly communicate with unusually large and numerous lymphatic or lacteal vessels. The lacteals become almost immediately connected with the largest group of lymphatic glands in the body. The muscular and fibrous wall of the vessel opens out, and becoming greatly increased in amount forms the capsule and trabeculæ, while the cell elements of the connective tissue forms the framework of the adenoid mass we call lymphatic gland. The substance is composed of lymphoid corpuscles multiplying with a rapidity which is measured by their food-supply from capillary blood-vessels and the passing stream of chyle; while their detachment is in proportion to the amount of distention by passing chyle. The greater the amount of chyle, the greater is the number of corpuscles added to it as it passes, each corpuscle being derived both in substance and properties from a pre-existing one, or, as in the original development, from the differentiated protoplasm of the endothelial cells.

Dr. Klein has described small cells which bound the stomata of serous membranes, cover the surface near the stomata, and often extend along considerable tracts of their surface. These are smaller than the ordinary endothelial cells and germinate freely under ordinary healthy conditions, but in such unhealthy states as are induced by the presence of pieces of gutta-percha or irritating substances injected into the peritoneal cavity, they germinate with great rapidity and form large villous projections on the surface of the membrane, the newly-produced cells falling into the cavity or presenting themselves in large numbers in the adjacent lymphatic vessels.

Thus, in the same way as in lymphatic and other blood-forming glands, white corpuscles of the blood are continually formed and thrown off into the stream of chyle or lymph, so under both normal and abnormal circumstances the cells bordering the stomata and covering parts of the surfaces of serous membranes multiply rapidly, while in inflammation not only these lymphoid cells, but the branched cells of the matrix also undergo very active proliferation. The natural food-supply of such cells is derived from the blood, the amount and rapidity of circulation of which is largely increased in some stages of inflammation.

I now ask your attention to the structural relations of the walls of blood-vessels to the tissue elements. The most cursory examination of blood-glands, such for instance as the spleen and the red marrow of bones, shows an important adaptation of these parts to each other. Ordinary capillaries, which are really little more than spaces between the elements of tissues lined by endothelial cells loosely cemented together at their edges, have frequently sinuous, spindle-shaped, or angular dilatations upon them, while their walls have projecting processes directly continuous with the branched connective-tissue corpuscles of the adjacent parts, a connection which shows the close similarity of the lumen of the vessel to the spaces of areolar tissue, while the endothelial cells of the vessel correspond to the less numerous but similarly flattened endothelial cells of the spaces, and to tendon and corneal corpuscles, which cover in an equally sparing manner their respective tendon or corneal spaces. Indeed, the whole lymphatic system, with its lymph canalicular spaces and its more definitely walled vessels, is neither a new nor an added system, but a part, and a most important part, of the general vascular system of the body.

If we trace a small artery in the spleen, we see the tissue of its wall opened out into spaces occupied by lymphoid cells, a veritable mass of adenoid tissue involving the whole or part of the circumference of the vessel, and when at length the vessel ends, it empties its blood into the spaces of the pulp bounded and supported by the flattened, branched, endothelial elements of the walls the commencing veins. Where the adenoid masses, the Malpighian corpuscles of the walls of the arteries abut upon the pulp tissue there is no separation, the elements of the adenoid reticulum and those of the walls of the sinuses being continuous, while the lymphoid cells of the adenoid tissue are free to mix with the venous blood in the sinuses. Here, as in the case of the lymphatic glands, the organ is subjected to great distention after the absorption of food, which not only leads to the formation and separation of large numbers of new lymphoid elements, but at the same time the cellular protoplasmic elements of the venous sinuses become very active, take up old colored corpuscles, break them down, and set free their variously oxidated remains into the blood stream. The vascular arrangements of the spleen, at the same time as they tend to retard the flow of the blood, are no doubt highly advantageous for the completion of the changes which the blood undergoes in the organ, while the necessarily tardy flow of the blood is no doubt compensated by the large size of both the artery and the

vein, and the loss of force by the rhythmical contractions of the organ so beautifully demonstrated by Dr. C. S. Roy. Lymphatic glands also have a muscular capsule and muscular trabeculæ, but as yet we have no evidence of their having rhythmical contractions.

I cannot pass without mention the largest living mass of protoplasm in the body—the liver—at one period employed in the production of blood-corpuscles, and then half the weight of the body. Originally formed upon the vitelline veins, and subsequently transferred to the umbilical, and then to the portal vein, as each in turn becomes the recipient of the food supplies, there can be no doubt that while its function is mainly to make and to maintain the blood, its methods of action still involve great physiological secrets.

From the preceding considerations it is plain that at certain parts of the circulating system for lymph and blood, lymphoid or white blood-corpuscles are produced in adenoid tissue from pre-existing corpuscles at a definite rate. If Quincke be correct in his supposition, that the duration of the functional activity of red blood-corpuscles is not longer than two or three weeks, we have in this a measure of the required productive capacity, for in healthy conditions a balance of the absolute and relative numbers of the corpuscles is very accurately maintained.

But this does not always happen. My late esteemed teacher and friend, Dr. Hughes Bennett, in his original description of leucocythemia, pointed out that an amazing relative increase of white in relation to the red corpuscles of the blood occurs in connection with enlargement of various of the blood-forming organs, and the disease is now universally recognized. In the second case, which came under the notice of Dr. Bennett, I had the pleasure of making the examination, and of recording and sketching the microscopical characters of the blood in the Pathological Reports of the Royal Infirmary of Edinburgh. In that case the spleen, liver, and intestinal glands were all enlarged.

In this disease there is a greatly increased production of lymphoid cells in situations where there is abundance of nutritive material, and this increased formation of corpuscles is possibly attended by a conversion of fewer white into red blood-corpuscles than ordinary, thus greatly increasing their numerical disproportion.

As lymphoid cells can also be produced in large numbers in and near the stomata, and on the surface of serous membranes, it is probably from such sources that the pus corpuscles of empyema and peritoneal effusions arise. And it may be asked whether the amœboid cells, which migrate through the walls of the blood-vessels on the onset of inflammation, possess the power of multiplying on surfaces which are now supplied with a largely increased amount of blood.

This is improbable for many reasons. Actual observation of such multiplication has not yet been satisfactorily obtained. Dr. J. Hamilton, in the record of his very interesting observations on the healing of ulcers and sponge-grafting, says that he has carefully watched the exuded leucocytes, and has never seen them get larger, either by over-nutrition or coalescence. Ranvier, who thinks it probable that lymph cells are connective tissue cells set free from adenoid tissue, believes that they will neither move nor multiply, except when freely supplied with oxygen; that the free supply of oxygenated blood by the capillaries of lymphatic and other blood glands, is the means of their multiplication, and that the absence of oxygen in the lymphatic vessels stops it. He sees in the rapidity of the circulation of blood an explanation of their migrating in small numbers only in health, while on the slowing or arrest of the circulation in inflammation they migrate in large numbers, and getting beyond the reach of the supply of oxygen disintegrate and cause coagulation of the plasma. He points to the experiment of introducing fragments of phosphorus under the skin, without arousing inflammation and migration of leucocytes, as indicating that the phosphorus has taken up all the oxygen present, and destroyed the amœboid movement necessary for migration, and thinks that the effect of cold in checking exudation is due to a similar action. Whatever the influence of oxygen on the manifestation of the vital movement of lymphoid corpuscles, it is certain that lymph differs widely from blood in containing a mere trace of oxygen.

In the formation of an acute abscess, the part is hot, painful, and swelled, exudation and coagulation of the exuded matter occur with migration of leucocytes through the vascular walls; the pain becomes more severe and throbbing, and the heat greater than before; next day there is indistinct fluctuation from the formation of pus, and from this time the pain and heat lessen, and the matter makes its way by softening and degeneration to the surface. The greater heat and pain preceding the formation of pus indicate greater distention of the vessels, and greatly increased exudation; or that the larger supply of blood which increased the pain and tension had furnished the food for the more rapid generation of lymphoid corpuscles.

When in diffuse phlegmon punctures are made one day and discharge thin serous fluid, and the next day the whole areolar tissue is distended with pus, there is little room for doubt that a rapid generation of lymphoid corpuscles has taken place at that very part and produced the pus. If this happen in one instance, it is probable that in other cases, too, pus is either formed by rapid proliferation of connective-tissue corpuscles, or that it is the result of rapid generation of corpuscles from those which first migrated, and that the primary cause of this is an increase of the normal attraction of the tissue for the nutritive matters of the blood, whereby the lymph stream flows more slowly and the corpuscles drag lazily along the wall, then penetrate it and escape with the plasma in large amount at a time when the cement between the endothelial cells has softened, and the spaces occupied by it have become widened.

But whatever be the cause, let us not lose sight of the main phenomena: millions of lymphoid corpuscles have been rapidly produced somewhere, and they have been produced from pre-existing corpuscles of the same kind. It will scarcely be suggested, without evidence, that the whole circulating blood has taken on either an entirely new, or, certainly, an unwonted action, in order to supply more lymphoid corpuscles than ordinary to the particular part where we find them accumulate; and it is little less difficult to maintain that, because of some local injury, a multitude of lymphatic or other blood-glands at a distance have produced a greatly increased quantity of corpuscles to migrate into the injured spot. We know that the period when the corpuscles of blood-glands multiply rapidly, and fall off in large numbers into the circulating current, is the period of tension and turgescence of such glands—a tension and turgescence produced by an extraordinary afflux either of blood, or of both blood and chyle. We cannot dissociate, either here or anywhere else, increased activity from increased supply of nutritive material, and we have no ground for supposing that there is an increased supply of nutritive material to the blood-glands because of a distant local injury. What remains? The admission is now as full and complete as I could wish in the instance of cartilage, that whatever changes take place in it are the results of the exercise of its own and of no borrowed power, and though some of the old leaven clings to the accounts we get now and then of the living actions of bone and tooth, I have no doubt that what is true of a living tissue, easily made the subject of observation, is true also of more complex ones, with whose elements other accessory tissues are mingled.

In the seats of formation of pus we have been considering, the corpuscular and formed tissue elements are ordinarily bathed in lymph transuding through the cement spaces of the endothelium of their vessels, and

having amongst it, here and there, amœboid corpuscles; now, a greater amount of blood than ordinary circulates through the vessels, these are dilated, the cement between their endothelial cells is of greater bulk and softer than ordinary; the fluid plasma and lymphoid corpuscles of the blood pass out into the tissue, which becoming tense and having its vitality impaired, acts as foreign matter to the effused fluid, and leads to the disintegration of some of its corpuscles and coagulation. Meantime the supply of nutritive material increases, the redness, heat, and throbbing become more intense, the part becomes firm and brawny with its increasing mass of corpuscles; and then, the violence of the action being over, and the vitality of the central part of the mass lessened by the tension, pallor and œdema, with great relief from pain, succeed; softening, degeneration, and solution of both tissue and exudation occur, and the fluid mass approaches the surface and points.

If it seem strange that the same process should produce necrosis at one part and rapid growth and multiplication of corpuscles at another, let us recollect what happens in the healing of ulcers. The surface is no longer supported by firm skin, therefore its vessels dilate and exudation occurs freely. Stimulated to unwonted activity, the connective-tissue corpuscles multiply rapidly; they first form rounded, then spindle-shaped cells, and ultimately the fibres, corpuscles, and ground substance of the new connective tissue of the cicatrix, while the exudation and the migrated corpuscles it contains disintegrate and soften into pus, which escapes on the surface. As the healing proceeds, the epithelial cells at the edge of the ulcer divide and produce others like themselves, which gradually extend over the surface and cover the newly formed connective tissue corium with an equally new epithelial layer, both having been derived from similar pre-existing tissue. The newly formed cicatricial tissue scarcely equals the old in bulk; therefore the surface is generally below the surrounding level, the ulcer healing down, not up, as Dr. J. Hamilton has expressed it, in his admirable demonstration of the changes attendant on the healing of an ulcer, in the *Journal of Anatomy and Physiology* for July, 1879, from which I have freely extracted these details.

Let us turn for a moment to the peritoneal surface, on which such a proliferation of cells as we have been considering has been going on for some time, and we shall have no difficulty in understanding that, while effusions may be absorbed by it with great rapidity as long as its stromata are healthy, when these are obstructed or obliterated by masses of proliferating corpuscles, the diaphragm, pump as it may, becomes entirely powerless to empty the sac of its fluid contents.

A very interesting case occurred to Dr. Whitla, of this town, in which obstruction and rupture of the thoracic duct led to the passage of the whole chyle into the abdominal cavity for several months. The surface of the peritoneum was everywhere studded with tubercles, and in consequence absorption of the fluid could not take place. It was removed by tapping at intervals in quantities of twenty pints or more.

The importance of the physiological arrangement by which the lung is irritated by lymph from the pleural to the vesicular and bronchial surfaces has, I think, not been sufficiently appreciated. The application of cold to the surface of the body produces general congestion of the lung, taking the form of pneumonia, pleuritis, or bronchitis, in different persons, according to their respective liabilities to these diseases. But the addition of one of these diseases to another which has been primarily produced is not as easy to explain by reference to their entirely different capillary blood-vessels as by the great freedom of communication of their lymph-passages.

Salivary secretion discharged after stimulation of the chorda tympani of a salivary gland deprived of circulating blood is no doubt derived from lymph previously stored in the gland itself; but under normal conditions this exalted action of the gland tissue is attended by the circulation of a greatly increased quantity of blood through it, a notable instance of afflux of blood attendant on increased vital activity of a tissue. The case of muscular tissue is exactly similar. I presume there can be no doubt that the increased activity of the circulation leads to increased transudation of lymph, which, however, does not coagulate, because the healthy limit has not been passed. But if the lymph had transuded into tissue which had been previously damaged, or damaged by the exudation itself, it would have coagulated as the veritable exudation of inflammation does.

When we call to mind that the cellular elements of capillary walls are continuous with the framework of lymph spaces, which themselves communicate through the endothelial cement with the lumen of the capillary tube, the continuity seems to reduce the question, whether the phenomena of inflammation depend on increased vital attraction of the tissue for blood or on some altered vital action of the vessels, to one mainly of words.

Yet the separation which is effected by the endothelial cement between the circulation of red blood-corpuscles in capillary vessels and that of lymph and white corpuscles only in lymphatic spaces is a real separation—a separation by a living colloidal septum of great liability to change. It suggests the necessity of a supply of oxygen and red corpuscles to some tissues, while others, such as cornea, have all their vital needs supplied by fluid plasma and white corpuscles.

If I have occupied much of your time on matters which I conceive to involve fundamental principles of physiology and its twin-sister pathology, and made free use of vital action, of which we cannot hope to learn more than the manifestations, let me plead the powerful influence of early impressions gathered from a most revered and philosophical teacher, the late Dr. Alison, who held that the essential peculiarity of inflammation is a peculiar perversion of nutrition or of secretion.

In the very pleasant examination of the border-ground of physiology and pathology, which the writing of this address suggested, nothing has been more forcibly brought before me than the clear insight which the painstaking and accurate investigations, and the genius of Sir James Paget gave him, long years ago, into many vital phenomena which seemed startling when they were spoken of individually. Thus, in his lectures at the College of Surgeons, from 1847 to 1852, he demonstrated many of the conditions under which exudations coagulate, or are restrained from coagulating, conditions which Mr. Lister's subsequent careful experiments have more fully elucidated in connection with the conversion of lymph corpuscles into granule cells, inflammatory globules of Gluge, a change first demonstrated by Reinhardt, and independently by Sir Andrew Clark. He pointed out that it is impaired nutrition, fatty degeneration, not death, which leads to absorption; he described most graphically the hardening of the wall of an abscess by coagulation of plasma, which neither the exuded corpuscles nor the fluid plasma alone could effect, and followed this by a clear account of the subsequent liquefaction of the hardened mass by what he styled "liquefaction degeneration," a great feature in Dr. Ziegler's more modern description and demonstration of what happens in the formation of a blister from a burn, and in the disappearance of clots of blood. And in the same lectures Sir James pointed out that granulations and clots of blood hinder the healing of wounds, leaving it for Dr. J. Hamilton, only quite recently, to prove this by irresistible microscopical evidence.

Knowledge derived from experience is never more interesting than when confirmed by scientific examination. Dr. Hamilton's paper on sponge-grafting recalled some of the earliest lessons of my professional life under a very able surgeon, the late Mr. R. C. Botham, of Chesterfield. He taught me to treat foul ulcers of the leg in workingmen by scrupulous cleanliness, a pad of lint steeped in solution of chloride of lime on the ulcer, then oiled silk

and a constantly applied bandage, making equal pressure from the toes upward, and kept wet with solution of chloride of lime. The success of this treatment was most marked, and I now see that, beginning with an absolutely clean surface, the dressings acted antiseptically; they prevented the contact of the atmosphere, and afforded the support which Dr. Hamilton has shown to be so essential for healing wherever the restraining pressure of the skin has been removed.

Dr. Cory's unfortunate success in vaccinating himself with matter taken from the cow-pox pustule of a syphilitic child, will lead to a reconsideration of the respective powers of development of the different constituents of the blood, and to the relations of its white nucleated to its colored non-nucleated constituents.

At the last meeting of the British Medical Association, Dr. Schäfer called attention very pointedly to the function of reproduction as belonging to the nucleus of a cell, and it is long since Dr. Beale showed the great power of the germinal matter as compared with that of the formed material of tissues. Yet for years the startling proposition has been maintained that syphilis is alone communicable in vaccination by the colored non-nucleated formed constituents of the blood. Every medical man knows the potency of the lymph taken early from a vaccine vesicle as compared with that obtained in the later stages when the lymph-corpuscles have degenerated into pus. And the previous considerations which I have urged upon you show that these lymph-corpuscles accumulated in the vaccine vesicle have been produced in this local inflammation either by migration and subsequent multiplication of the white corpuscles of the blood or by active proliferation of the connective-tissue corpuscles of the part; in either case from germinal matter, active, living protoplasm, if not by the direct agency of the nuclei of such matter.

Recalling Mr. Goodsill's happy demonstration, that the cells of lymphatic glands are developments of the epithelium of lymphatic vessels, and Dr. Klein's beautiful tracing of endothelium and the corpuscles of connective tissue at the fenestræ of omenta and in other situations, we recognize the family relationship between the lymph-corpuscles which, when detached, constitute white corpuscles of the blood—the endothelium of serous membranes so often found germinating abundantly—and the connective-tissue corpuscles, which Dr. Hamilton has figured and described as multiplying with great rapidity when stimulated by the agents causing inflammation and unduly fed by a largely increased afflux of blood.

If it be asked why syphilis does not more frequently follow vaccination, the reply is simple, that the greatest care is taken to select none but perfectly healthy children for the collection of lymph, and that it is possible that when lymph has been collected where syphilis, though present, was not recognized, the results may not always have been referred to their proper causes.

This leads me to mention the most difficult, exciting, and important problem of the day: whether other diseases than small-pox can be deprived of their virulence by vaccination.

You are aware with what ardor M. Pasteur has espoused the affirmative side of this question, and it was very natural that, having had a certain amount of evidence that infectious diseases of animals may be deprived of their fatal effects by previous vaccination, he should have been led to hope that what is true of one is true of all, and that in this way even hydrophobia may be deprived of its horrors.

The exceedingly careful researches of Dr. Klein, described with such accuracy of detail that they may be followed by any one, have shown that there are numerous pitfalls in the way of such inquiries, and that we are yet very far from being able to foresee the end of them. Yet the progress made gives great hope for the future, for careful experiments by Drs. Klein and Roy, and by Dr. Burdon-Sanderson and Mr. Duguid, have clearly shown that sheep inoculated with anthrax blood of the white mouse, cattle inoculated with anthrax blood of the guinea-pig, and cattle inoculated with anthrax blood of the South American bisachas are, for a time at least, insusceptible of a fatal attack of the malady.

Dr. Klein has found that the virus which communicates swine disease is a form of bacillus which he has been able to cultivate out of the body in various ways, and which is capable of forming spores when exposed to the air. But though the organs of a dead animal swarm with the bacilli, these soon degenerate and become harmless, without forming spores, if the body be not cut, and this happens equally whether the body be interred or not.

From long experience I am satisfied that the bodies of persons who die of small-pox, or of puerperal or other fevers, may be dissected without harm if properly prepared.

Dr. Burdon-Sanderson has suggested the possibility of the determination of the morbid process in contagious diseases by an action similar to the spontaneous arrest of septic fermentations by the development of members of the aromatic group of chemical compounds destructive of any further manifestation of the vital activity of septic microphytes, and he has undertaken to direct a series of researches on this subject.

On the one hand, what can be more alarming than that, under certain conditions, living organisms of the utmost minuteness enter the body and multiply with a rapidity with which fungi alone can multiply, corrupting the blood, causing local coagulations, obstructions of vessels, abscesses, and death? and, on the other hand, what can be more comforting than Dr. Sanderson's happy reference to the manner in which salivary, gastric, or pancreatic digestions furnish the means of their own arrest, and to the similar manner in which the organisms containing the virus of contagious diseases prepare the means of their own destruction?

Surely the day will come when it will be seen that gratitude and reverence are due to such men as Pasteur and Koch and Sanderson and Klein, rather than that they should be assailed with insult and hindered by mischievous legislation, as if they were criminals rather than benefactors of the whole human and animal races.

Let me mention certain circumstances which I think indicate that we are on the eve of great simplification and extension of our knowledge. It was a great step when the late Master of the Mint taught us the difference between crystalloids and colloids, and many of the laws of diffusion and osmosis. It led the way in an intelligent investigation as to how, in the process of digestion, colloidal starch and albumen are fitted to pass through the membranous walls of the alimentary canal. We have found that contact with a mere trace of saliva or pancreatic or intestinal secretion suddenly converts starch into sugar, and that a large number of other organic matters produce a similar result. Bernard showed, by experiment, how different cane, grape, hepatic, and diabetic sugars are in their relation to the economy; that starch and sugar are converted into fat by the liver; and that by an insignificant lesion of the medulla oblongata temporary diabetes can be produced. And we know, further, that during the conversion of starch into sugar there are many almost insensible stages. The process is influenced by numerous conditions which require investigation at every step to enable us to trace these substances at their entrance into the economy, in the regions where they contribute to the production of heat and motion, and until their final deposition or discharge in some more oxidated form.

Similarly I would suggest the most careful observation—not by one person, but by every one in his own sphere—of the conditions under which albuminoid matters are changed, whether after their entrance into the upper or lower end of the alimentary canal; of those under which they pass into the blood, circulate, and become tissue;

also of the forms under which they reappear in their variously oxidated conditions in the urinary excretion in health and disease.

The marvellous differences between albumen of the egg and serum and albumen washed free from salts, or when changed into acid or alkali albumen; the modes of production of peptone and its varieties; the differences in the conditions and results of the action of the gastric, pancreatic, and intestinal secretions; and very specially the appearance in the urine, in disordered or diseased conditions, of albuminoid substances yielding reactions, showing that the variety of forms in which these substances appear are no less numerous or closely related than those of the varieties of sugar and starch, all point to the necessity of rigorous investigation, and to the possibility of presenting these substances and their various alternations in a light far more simple than has as yet been suspected.

It is unfortunately the custom in this country to leave such investigations to be undertaken by private individuals, very few of whom have the necessary physiological and chemical knowledge, and fewer still have the requisite time and means at their disposal. That we have men admirably fitted to direct and aid or to conduct such inquiries is plain from the researches of Simpson and Thudichum and the aid rendered by Gamgee, Ralfe, and T. C. Charles. And I am not without hope that the public spirit of this great country may yet be aroused by the expressed opinion of the President of the Royal Society and others as to the duties of the state in such matters, and that something worthy of the nation may yet be done to aid the teaching of science and to promote scientific inquiry.

PRACTICAL OBSERVATIONS ON THE HUMAN EAR AND ITS DISEASES, WITH ILLUSTRATIVE CASES.

By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I.—The External Ear.

(Continued from No. 713, p. 7.)

HÆMATOMA AURIS—SYMPTOMS.

The affection may begin in either ear, but most frequently attacks the left; both ears are sometimes attacked about the same time, the left, however, being usually, it is alleged, the first to exhibit symptoms of invasion. The exudation always takes place, as far as my own experience goes, on the outer surface of the pinna, and seldom affects the inner surface at any period of the disease. The swelling in most cases begins near the superior border of the pinna, but it may show itself on any portion of the exterior surface, including the concha. The lobule is never directly affected, since it contains no cartilage, and the cartilaginous portion of the external auditory canal is seldom involved. The tragus seems to enjoy entire immunity from attacks.

This selection of the outer surface of the auricle seems to be owing to the greater vascularity of this region, upon which the branches of the anterior and posterior auricular arteries ramify and anastomose, and to the fact that it almost invariably receives the impact, when the auricle is struck, with greatest force. Where there is an inflammatory movement in the parts, the connective tissue on the inner surface of the pinna may become the seat of suppurative action and an abscess may form; or, should perforation of the cartilage take place, the contents of the tumor may pass through from the anterior cyst, separating the perichondrium from the cartilage on the inner surface, and escape into the connective tissue even.

When the invasion takes place the affected region usually presents a hyperæmic appearance; frequently there is in lunatics a very decided flow of blood toward the head, producing great capillary turgescence of the face, ears, and eyes; in some instances an effusion of blood beneath the conjunctiva of the eye has been known to occur simultaneously with the appearance of the othæmatoma. In the more severe cases, where the characteristic effusion takes place rapidly with inflammatory action, there is often an elevation of temperature; and in nearly all instances the integument assumes a bluish or purplish hue. The affected organ is seldom very painful, even where the tumor is greatly distended or roughly handled, especially in boxers and lunatics, where the parts have been subject to rough treatment from repeated contusions; in the latter, however, the ears are wanting in sensibility at all times. The writer has, however, frequently observed that sensibility is very much exalted in some cases occurring in sane persons.

The progress of the tumor varies very much; it may rise to a considerable size in the course of a few hours, and when first seen may be as large as an almond or a walnut. Sometimes the distention continues to progress rapidly, the walls becoming thinner in consequence of the stretching, until, finally, in the worst cases, they undergo spontaneous rupture unless relieved by an operation. In asylum cases it is not unusual to allow the cyst to burst in this manner; thus of the twenty-four cases reported by Hun fifteen ruptured spontaneously; in one of them the left ear burst on the twelfth day at the upper part of the concha, while the patient was sitting in a chair, and the contents "were thrown to the ceiling, a distance of twelve feet, so as to stain the plaster."

These tumors are, however, frequently without some of the symptoms of inflammatory action, passing through all of the stages of the disease without either heat or pain being experienced by the patient. This variety manifests a disposition to develop slowly, and has a tendency to spread itself laterally rather than in thickness. The following case is one of this description:

Case I.—W. W——, an Englishman, forty-three years of age, by occupation a negro minstrel; health good, and he claims to have no bad habits; never had any aural disease before; came to the New York Eye and Ear Infirmary May 4, 1880. States that two weeks ago, while washing the burnt cork from his face, he felt a slight soreness on the top of the right auricle. On examination he found a small tumor on the outer aspect of the auricle, which afterward gradually increased in size until it was larger in diameter than a twenty-five cent piece; it then obliterated the antihelix, and finally became about one-half an inch in thickness. On shak-

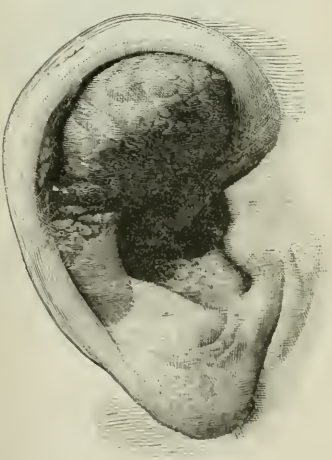

Fig. 1.

ing his head the patient could "feel the contents of the tumor rattle."

Dr. Henry D. Joy, to whose kindness I am indebted for the case, had painted the tumor with the tincture of iodine for the first few days, and it had decreased somewhat in size. When the iodine stains disappeared the color of the tumor was found to be but little more red than normal, but its walls were thickened. Under the expectant plan the fluid continued to be reabsorbed quite rapidly, and later on the contents had a doughy feel.

June 4th.—The patient himself has occasionally painted the ear with tincture of iodine, and for the past two weeks it has diminished notably in size. Thickening and immobility of the integument, however, remain. There is no shrivelling of the cartilage, and but little deformity from the remaining induration of the parts. It is the belief of the patient that the auricle, previous to the beginning of the swelling, had been struck a slight blow by a papier-maché stove, which he had to throw upon his shoulder during a play.

Fig. 1 represents the appearance of the ear immediately after the tumor had commenced to subside.

In some instances, however, cases like the above, after remaining *in statu quo* for a variable period of time, suffer an exasperation from repeated contusions, and an othæmatoma of very considerable size may be developed. Such an aggravation may also be brought about by injudicious operative procedures, or probably by an exacerbation of cerebral symptoms, giving rise to increased activity of the general circulation about the head and ears.

In the beginning of an attack, and during its progress, the patient sometimes experiences a feeling of heat in the affected organ, like the extreme congestion due to flushing; in the insane, however, precursory signs are not likely to be reported.

Generally the outlines of the outer surface of the pinna, formed by the foldings of the cartilage, are more or less obliterated, according to the extent of the tumor; where there were ridges and depressions before, the surface will be smooth—usually convex even.

The contents of the tumor, in the beginning, may consist of blood and serum, or of the latter principally; even when at first serous, the fluid usually becomes serosanguinolent sooner or later. In some instances, however, the serous character continues throughout. In most cases an early formation of coagula takes place in the tumor, which, not being reabsorbed, increases ensuing deformity. In the milder form of the affection, sometimes described as "œdematous," but little fibrous tissue remains, reabsorption being more complete; such cases seem to pass through all of the stages with but moderate inflammatory action.

The wound which affords an outlet for the contents of these cysts, when they require any, whether from puncture or due to spontaneous rupture, has no tendency to remain open, and the cavity, therefore, sometimes refills in the course of a few hours; on the other hand, in certain cases the cyst pours out fluid so rapidly that a discharge constantly trickles down from the opening, thus preventing the wound from closing.

The duration of othæmatoma will of course vary greatly, depending as it does on the severity of the case, the rapidity of reabsorption, and the habits of the patient; thus in lunatics, inebriates, and boxers the organ is liable to repeated contusions, giving rise to aggravations which may retard the cure. Sometimes reabsorption comes to a stand-still, and a considerable tumor remains for an indefinite period of time.

The writer has seen a case of this kind which is given below:

Case II.—Charlotte K——, aged thirty-nine, was admitted to the New York City Lunatic Asylum in May, 1880, when suffering from her first attack of acute melancholia. She had delusions of persecution and suicidal tendencies, was subject to exacerbations of excitement, during which she was violent and destructive until quieted by large doses of sedatives. In June, 1883, hæmatoma commenced in the left ear, which ran its course in two months without any particular treatment, leaving much deformity. On September 12, 1883, othæmatoma commenced in the right ear: at first it was intensely red, but finally became purplish in appearance. No treatment.

October 31st.—The patient was examined by the writer and a considerable collection of fluctuating fluid was detected in a cyst an inch in length, on the outer surface of the right auricle. It was recommended that the fluid be evacuated by a rather free incision, the walls of the cyst painted with Churchill's solution of iodine, and the auricle bandaged to the head so as to cause a moderate amount of pressure. This was done by Dr. L. C. Toney, though through some misunderstanding three successive applications of the iodine were made. By November 3d the walls were adherent, and on November 9th the wound was found healing by granulation. When the writer last saw the ear, on November 23d, it was found that the sac was entirely obliterated. The cicatrix was slightly stained from the excessive use made of the iodine solution. There was scarcely any deformity.

In some instances a sinus remains, affording a serous discharge which may continue for an indefinite period. The following is a case of this kind:

Case III.—Annie M——, aged thirty-five, was admitted to the New York City Lunatic Asylum, March, 1879, with acute mania. Soon afterward, on refusing food, was forcibly fed—the process consisting in placing the head of the patient under the left arm of the operator, while with his left hand a wedge is held in the patient's mouth, and with the right hand the feeding-tube is inserted. Subsequently hæmatoma developed in the left ear. Although it seems probable that the ear was bruised during the forcible feeding, yet the patient was frequently engaged in fights with other patients at this time, when she was liable to receive blows upon the ear. There was no treatment, and the tumor passed into a chronic stage, which escaped observation until September, 1883, when serum was observed to ooze from an opening in the outer surface of the auricle just above the concha. This opening was enlarged and the cavity syringed out with a solution of carbolic acid with no result. On October 19th the writer examined the case and determined to obliterate the sac by an operation. The sac was laid freely open, cleansed of the copious flow of blood and other contents, and the walls were then thoroughly painted with Churchill's solution of iodine. Notwithstanding the employment of such pressure as was found to be practicable, the parts healed up again, leaving a small sinus as before. Subsequently the operation was tried three different times by Dr. Dent, the assistant superintendent, without avail.

Fig. 2.

November 23d.—The writer finding a slight sero-sanguinolent discharge remaining, concluded to try to obliterate the tumor by scraping its walls with a cutting-scraper. It was found, however, that the walls of the sac, which proved to be very large, consisted of broken-up and shrivelled cartilage, presenting rough and uneven surfaces. A partly detached plate of cartilage was found lying on the outer wall, and the edge of the superior portion of the helix could be felt. There was a deficiency in the cartilage composing the inner wall of the sac. It was evident that the irregularities of the walls had prevented adhesion of the surfaces from taking place.

Operation.—With scraper (Fig. 2) every portion of the secreting surface was destroyed, considerable broken-down tissue being brought away by the instrument, which had to be cleaned several times. The oozing of blood was quite profuse for a time. The parts were thoroughly cleansed with hot water, and pressure established by bandaging the padded ear firmly to the side

of the head. It was noted that throughout the operation the patient seemed to experience no pain whatever. No anæsthetic was employed. The parts healed kindly, pressure was maintained for some time afterward. After the first week there seemed to be some improvement, but when I saw the patient, on December 22d, the cure was incomplete. It is very evident that union can only be obtained between the walls of the sac in this case by dissecting out the irregular and detached masses of cartilage which prevent them coming together.

In a very considerable number of cases the disease will terminate spontaneously in from four to eight weeks, depending somewhat on the extent of perichondrium affected and the quantity of the effusion; othæmatoma, however, cannot be said to have any regular course where it occurs in irresponsible or uncontrollable patients.

Subjective symptoms.—These usually are present where occlusion of the external auditory meatus is produced by swelling of the concha; they consist in deafness—due to closure of the canal—and tinnitus aurium—from increased tension of the membrana tympani. The extent of these symptoms in lunatics cannot with accuracy be determined.

Complications.—The retroactive consequences of this local trouble in the insane need not be considered here, yet it is worthy of note that the posterior auricular artery, through one of its branches—the stylo-mastoid—communicates with the middle meningeal by anastomosis, thus establishing a significant and important relationship between the ear and the meninges of the brain. In the mentally sane this becomes a factor of serious import, and should not be overlooked; besides, more or less general nervous sympathy may exist in sane patients.

Parts contiguous to the ear are sometimes implicated in an extension of the inflammatory process; neuralgia may be kindled into action, and general febrile action may supervene. Whilst othæmatoma may be produced by disease or wounding of the cartilage of the external auditory canal, it seldom extends itself to these parts from the pinna; and the middle ear, so far as is known to the writer at least, has never been invaded by an extensive inroad of the inflammatory process.

DIAGNOSIS OF OTHÆMATOMA.

The "Asylum Ear" was, by all observers half a century ago, regarded as a curiosity simply, and even at the present time it seems to very often escape attention entirely, or to be merely entered in asylum case-books as a nondescript phenomenon. It is to be hoped that a want of knowledge in this respect will not long prevail where the disease is liable to occur, and where treatment may do much to ameliorate the condition of the patient. In fact, the want of adequate knowledge in regard to othæmatoma seems scarcely any longer excusable when we consider the light that has been thrown upon the subject during the past twenty years by various authors.

In distinguishing this affection from erysipelas, phlegmonous inflammation, frost-bite, burns, eczema, tubercular syphilis, and other cutaneous affections one almost constant causative agency should be first sought for, namely, trauma. Whether predisposing conditions are present or not, the history will give unmistakable evidences of this factor. There may often be reasons for suppressing the truth; persons may desire to conceal the facts of blows having been administered, or they may have been so slight as to have escaped attention, nevertheless where othæmatoma is suspected, inquiries in this direction should be diligently pressed.

The essential nature of the affection depending on a perichondritis of the cartilage of the auricle, its existence may be readily detected by examining the contents of the tumor, which will be found to be serous or sero-sanguinolent. These tumors are usually of rapid formation, and speedily refill again on being evacuated. It will be found that they have well defined and resisting walls, a fact which may be determined by exploring the walls of the tumor with a probe after it has been incised or ruptured.

Abscesses or blood extravasations rarely develop in the scanty connective tissue of the auricle, and they are much more limited in dimensions than othæmatoma; their walls, moreover, give way to moderate distention, and their progress will be found to be less protracted than the tumors under consideration. The serous or sero-sanguinolent discharge which characterizes othæmatoma, could not have its origin in a cavity formed by the breaking down of the connective tissue by effused blood, but must arise from a secreting surface.

Suppurative perichondritis has been alluded to by writers, but it is difficult to see how pus could be secreted by these cysts; extravasated blood may, however, become putrescent, or a perforation of the walls of the cyst may afford a communication with an abscess behind the cartilage of the auricle, or with the deeper parts about its attachment to the temporal bone.

Abscesses, however, may develop in the post-auricular connective tissue during the progress of cases of marked inflammatory tendency or as a result of contusions. In such cases, or where swelling occurs without maturation, an asymmetrical prominence of the auricle occurs.

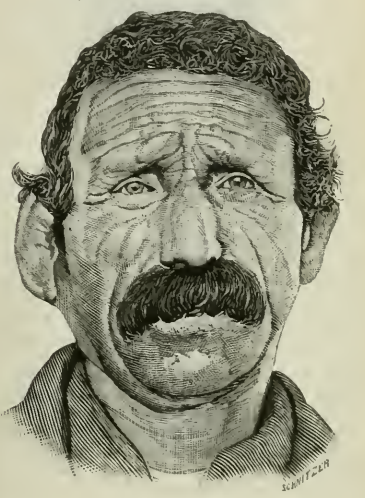

Fig. 3.

The following case is in point. Fig. 3 is an excellent likeness of the patient, and Fig. 4 is a view of the post-aural abscess, natural size.

Case IV.—Michael F——, thirty-five years of age; married; intemperate; entered New York City Asylum for the Insane, with dementia, 1872. Is morose and stupid. In 1878 found to imagine that he had a woman in him. In 1882, delusions of dead bodies in his head. April, 1883, extravagant delusions, as head filled with articles of food. The eyebrows have almost disappeared from constant rubbing, tries to rub his eyes out. November 24, 1883, hæmatoma of the right pinna observed. Continually rubs side of head with stones and beats himself. November 25th, the tumor on inner surface of auricle was incised. . . .

I saw this patient on November 27th, and the following is an abstract of the notes taken by Dr. Robert Barclay, who assisted me: The right auricle is thickened, the outlines of the outer surface being almost obliterated. The whole organ is red and tender, although sensibility is much lowered. A large fluctuating abscess occupies the lower half of the inner surface of the pinna, and extends downward, spreading out over the mastoid process and involving the lobule. There is a slight indentation where incision was made on the 25th. It has been treated by

applications of iced water. The writer made an incision, about half an inch long, into the lower part of the abscess, evacuating about a fluid ounce of pus. The teeth of this patient were very carious, quite so on the right side, and were all of them enveloped in much

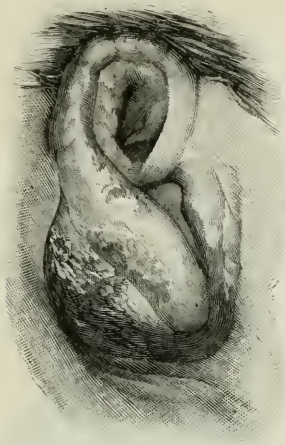

Fig. 4.

tartar. It would seem that the post-aural abscess, although consecutive to the othæmatoma, was due to the constant bruising of the parts by the patient himself. The othæmatomatous tumor on the exterior surface of the auricle probably gave rise to unusual vascularity in the whole organ, and there may have been an opening in the cartilage permitting the passage of the contents of the cyst into the connective tissue behind the ear, but there was no evidence of any separation of the perichondrium from the cartilage on its inner surface, and the contents of the abscess apparently contained no serum. There was no history as to the exact duration of the othæmatoma.

In many cases of othæmatoma the auricle does not stand off from the head, the disease being limited to the wing of the ear throughout. Parts contiguous to the auricle are always the last to be affected, if invaded at all. The trouble may be distinguished from erysipelas, for which it was formerly sometimes taken, by its well-defined sacculated appearance and the absence of superficial changes common in erysipelas. Eczema and erysipelas, unlike othæmatoma, are liable to extend into the external auditory canal, while the latter, at most, usually, occludes the meatus by the encroachment of its sac. The cutaneous affections mentioned above, moreover, frequently invade the neighboring parts, especially the inner surface of the auricle; none of them, however, leave the deformity which characterizes othæmatoma. Nævi may resemble othæmatoma very closely in some instances. Dr. Gorham Bacon showed the writer a case of this kind occurring in a woman where a large portion of the auricle was involved. The marked pulsation and absence of fluctuation in such a case would serve to distinguish it from othæmatoma. The age of the patient should be considered in arriving at a diagnosis; thus eczema is most frequent in infancy and childhood, whilst othæmatoma is more particularly a disease of adult life. Cases of othæmatoma, it is true, have been reported as occurring in children; one of them, it is stated, occurred "idiopathically" in a child one year and three months old, where an otorrhœa and eczema of the external auditory canal preceded the attack.[1] The writer has never seen a case of this kind, and is convinced that their occurrence is extremely infrequent.

(To be continued)

ON RESPIRATORY MEDICAMENTS.

By Professor GERMAIN SÉE,

Member of the Academy of Medicine, and of the Faculty of Medicine, Paris, France.

Pneumotherapy constitutes an artificial respiratory method, calculated to facilitate respiration as well as the central and peripheral circulation. It comprises the fixed respiratory apparatuses, known for many years, but whose effects on the heart and circulation have less engaged the attention of observers than the action of these artificial atmospheres on respiration and nutrition.

Pneumotherapy, in its more modern development, is practised by the aid of portable apparatuses, invented by Waldenburg, with more precise and special applications to diseases of the heart and blood-vessels.

Effects of Normal Inspiration and Expiration on the Thoracic Organs.

Respiration in free air exercises a marked influence on the circulation.

Inspiration.—The pulmonary air is in a state of diffusion, and thereby exercises an aspiration or suction on the vascular system in such a manner that during inspiration the venous blood arrives with greater facility and speed from the head and trunk to the thorax and heart; the latter dilates easily to the inflowing current. During this period, nevertheless, the expulsion of blood from the heart takes place with less energy, and for this reason vascular tension diminishes during the inspiratory act.

It is only at the end of inspiration that the pressure of the pulmonary air becomes equal to that of the atmosphere, and then the modifications in the circulation, effected by inspiration, end.

Expiration.—Here everything is reversed; the thoracic parietes sink in, compressing the air in the lungs which undergoes condensation; there results at the same time a pressure on the heart and great vessels. The venous blood flows with difficulty into the thoracic cavity and heart, the veins of the body swell; the contractions of the heart take place with more energy, but without power to force a great deal of blood into the arterial tubes.

Effects of Inspiration of Compressed Air.

Mechanical effects on the lungs.—The inspiration of compressed air determines at first a sensation of plenitude and distention in the thorax, resulting from the expansion of the lungs and the entire thoracic cavity, an expansion which is more marked than that which follows the most powerful voluntary inspiration, although the inspiratory muscles do not in this case put forth any sensible effort. The compressed air which penetrates the lungs begins by diffusing itself with the residual air in the lungs, and it is not till the end of inspiration that it reaches the degree of pressure which it had in the apparatus. The quantity of air introduced into the lungs and then eliminated during these inspirations of compressed air amounts to one thousand cubic centimetres, according to Waldenburg, and according to Speck, to seven, eight, and even ten thousand cubic centimetres each minute; this explains the thoracic enlargement, which may exceed the normal by four centimetres. The lungs become thoroughly permeated with air, and clear themselves of bronchial mucus. Still later, both inspiratory and expiratory force is increased, and this, not only during the pneumatic treatment, but for some time after.

The same may be said of that increase of vital capacity which results from treatment by compressed air, it lasts for a considerable time. The condition of success is not to exceed $\frac{1}{10}$ of the atmosphere pressure, for if this condition be not observed serious accidents may occur, such as loss of elasticity of the pulmonary tissue, pulmonary emphysema, and hemorrhages from rupture of blood-vessels, if the lung-tissue be at all altered.

Effects of inspiration of compressed air on the heart and circulation.—[The entire subject of the physiological

effects of inspiration of compressed air demands revision and restatement. No one has acknowledged this more plainly than Professor Sée himself, when, after a long and interesting statement of Waldenberg's theory, he confesses that it has been overthrown by recent sphygmographic explorations. This being the case, I have taken the liberty to omit this portion of Professor Sée's lecture, for, however reasonable any theory may be, if it will not stand the test of facts it is worth nothing.

Waldenberg established the following laws: Inspirations of compressed-air augment the pressure in the entire arterial system; expirations in rarefied air diminish the pressure in the aortic system. Lambert, Ducrocq, Riegel, Franck, Zuntz, and others, by a carefully conducted series of experiments, arrived at opposite results.

Dujardin-Beaumetz, in summing up the results of experimentation, thinks that compressed air has often a very favorable effect on the respiration, producing a current of air through the air-passages which clears them of mucosities, and gives to the pulmonary parenchyma a new elasticity. The vital capacity is augmented, as is shown by the spirometer. On this point, Waldenburg is in harmony with all other experimenters. As for the effect of compressed air on the circulation, the opinions are so contradictory that nothing very reliable can yet be determined; it is by no means demonstrated that this therapeutic method is of any efficacy in diseases of the heart, while its utility as a respiratory medicament in chronic bronchitis, asthma, emphysema and phthisis is unquestioned.—Tr.]

Experiments on animals by most painstaking observers, such as Einbrodt, Hering, Drosdorf, Lambert, Zuntz, have cast great doubt on the theory of Waldenburg, seemingly so reasonable. Clinical observations, aided by tracings of the pulse, have confirmed the conclusions derived from physiological experimentation. These experimenters made use of the kygmograph, a sort of manometer, introduced into the arteries in animals. In all the conditions which to Waldenburg indicate an augmentation of arterial pressure, they constantly found a lowering of vascular tension. Where a diminution of pressure had been noted experimentation showed an excess of pressure. Waldenburg sought to explain this discordance by saying that the tension of the vessels and intravascular pressure are not correlative terms, and that sometimes the tension of the arterial walls augments while the blood-pressure diminishes. He sought to make this demonstration by means of an instrument designed to measure the degree of arterial tension, and which he called a "pulse-shower" (*montre du pouls*). The downfall of the theory was nevertheless complete.

Clinical and sphygmographical observations.—Clinical observations have conclusively confirmed the results of experimentation. Riegel and Franck distinguish two opposite periods, the one of the initial phenomena, the other a final period, which is the most important. Their results agree with those of Ducrocq, Drosdorf, and Zuntz. Omitting the somewhat tedious details of sphygmographic tracings (for which I refer you to my work on "Anomalous Forms of Heart Disease") these careful observers are unanimous in affirming that the first effect of inhalations of compressed air is to produce a diminution of intravascular tension, with diminution of the frequency of the pulse; as soon as the atmospheric pressure on the lungs, the heart, and blood-vessels diminishes, the blood-pressure rises.

It results from these observations that, while Waldenburg taught that compressed air was a means of fortifying the heart, by a sort of regular gymnastic exercise, the observers cited above, and especially Oertel and Schnitzler, have never noted such effects, especially in the application of pneumotherapy to diseases of the heart.

Dynamic effects.—According to Sommerbrodt and Biedert, the intra-alveolar air, by the exaggerated pressure which it exerts on the respiratory mucous membrane, produces on the sensory nerves of the lungs an impression which, by reflex action, excites the vaso-dilator nerves, in this way diminishes the vascular tonicity, dilates the blood-vessels, and lowers the pressure. On the other hand, the inhibitory nerves of the heart are enfeebled, and there is quickening of the heart's action and of the peripheral circulation; the intra-alveolar pressure thus becomes the regulator of the velocity of the circulation.

Chemical effects.—Every change of pressure in the inspired air or in the expired air determines increase of activity in the respiratory process; but the elimination of carbonic acid is always more marked than the absorption of oxygen, so that more oxygen is eliminated than was introduced previously. The action of inspired or expired air, then, resembles the voluntary augmentation of ordinary respiration, and the modifications ought not to be considered as the result of more energetic oxidations, but only as the consequence of a more complete diffusion of gas, abstraction being made of the muscular action (which is of little significance) during this more active respiration. These facts were long ago pointed out by Paul Bert.

RAREFIED AIR.

Expiration in rarefied air.—Expiration in rarefied air produces a very distinct sensation of retraction of the thorax. The abdominal viscera and diaphragm are drawn upward into the thorax by a sort of aspiration. The lungs are very thoroughly emptied of their atmospheric contents; even large quantities of residual air are eliminated, from five hundred to two thousand cubic inches, and even three thousand in the emphysematous.

It is easy to understand that by reason of this elimination the volume of the lungs is reduced. The expelled air issues in greater volume and the inspired air penetrates with greater facility; the inspiratory muscles are little taxed.

The contraction of the pulmonary area is shown by the cyrtometer, and amounts to from one to two centimetres of circumferential measurement. The retraction of the epigastrium, and especially the elevation of the diaphragm, recognizable by percussion, are, moreover, a proof of this narrowing of the field of respiration.

By long continuance in the practice of expiration in rarefied air an increasing augmentation of vital capacity is noted; this may, in the emphysematous, amount to five hundred, and even one thousand cubic centimetres. It is easy to detect, by the pneumatometer, an increase in the force of both inspiration and expiration—the latter by virtue of the less resistance which the elasticity of the pulmonary tissue and the muscles of expiration have to overcome.

Effects on the circulation of expiration in rarefied air.—These are similar to those of inspiration in free air. The venous blood more readily returns to the thorax and heart, the veins are emptied while the thoracic viscera are filled. The work of the heart becomes more difficult and the ventricular systole is weaker, pressure in the arterial system falls and the arteries are less tense and more compressible, the pulse is small and soft, and while the lesser circulation is overcharged, the greater circulation is poor in blood.

The nervous system is more irritated and reflex vaso-motor action is more marked than when compressed air is breathed.

Inspiration of rarefied air.—This ought to act on the circulation like inspiration in free air, and like expiration in rarefied air, but with more intensity. It is readily understood that more effort is required on the part of the muscles of inspiration to introduce the necessary quantity of air than when ordinary air is breathed; hence the respiratory muscles become strengthened by a sort of regular gymnastic exercise. The ventilation of the lungs, according to Waldenburg, is diminished; according to Speck it is augmented.

Expiration in compressed air.—By expiration in com-

pressed air the expulsion of air from the lungs is rendered more difficult. Here the muscles of expiration are called upon for more work. According to Speck, pulmonary ventilation is augmented, as it is by inspiration of compressed air, for although an obstacle to free respiration exists, this is overcome by the enhanced action of the breathing muscles, and air enters in great abundance. The organs of circulation are modified, as by inspiration of compressed air.

APPLICATIONS OF PNEUMOTHERAPY TO DISEASES OF THE HEART.

Waldenburg, Henich, etc., recommend inspirations of compressed air in certain cases, directing from fifty to one hundred inspirations, of $\frac{1}{100}$ to $\frac{1}{60}$ above the atmospheric pressure. The utility of these inspirations in any form of heart disease is doubtful. When you have a case of mitral disease with perfect compensation, compressed air is not necessary. On the other hand, if compensatory hypertrophy has not commenced, or if it is insufficient, compressed air removes the *besoin de respirer*, the dyspnœa, the congestions of the lesser circulation, the palpitations, and the cyanosis. This effect may be far more lasting than the period of inspiration. During the inspirations of compressed air the excess of pressure on the part of the air drawn into the lungs causes expulsion of the blood from the pulmonary vessels, and a clearing of the lesser circulation. Compressed air is then useful (*a*) to augment the systole and the arterial pressure, (*b*) to facilitate the passage of blood from the heart, (*c*) to render more difficult the access of blood from the great veins to the heart, and thus to free the lungs.

In these cases, says Oertel, it is preferable to expire in rarefied air, for then the vascular pressure and the tension of the arterial walls are augmented during the entire expiration, and stases in the peripheral veins are prevented, while the heart's energy is promoted by a more easy diastole. All this is uncertain and theoretical, the result, it must be confessed, of rather hazardous assertions, based on two successful cases reported by Henich and Schnitzler.

Aortic insufficiency and constriction.—In both aortic insufficiency and aortic constriction (according to Waldenburg) the dyspnœa is diminished because the intrapulmonary pres ure clears the blood-vessels of the lungs, before engorged; but the facts cited by Waldenburg have no value.

Fenoglio, in fact, denies the utility of compressed air in these affections; he thus formulates the application of pneumotherapy: In aortic insufficiency with excessive activity of the left ventricle we have an indication for expiration in rarefied air. We hope in this way, he says, to diminish the exaggerated compensation, and he cites three cases in support of this method of treatment. Under the influence of these expirations in rarefied air he has seen tension enfeebled and the arterial engorgement lessened; at the end of the expiration the sphygmographic elevation of the blood-wave was diminished, the line of descent became less vertical, and dicrotism was less marked. Little by little the palpitations diminished also, as well as the painful arterial pulsations and the feeling of anxiety and precordial distress.

Fatty degeneration.—Several cases treated by Waldenburg were benefited by compressed air.

Pulmonary cardiac hyperæmia, with hæmoptysis.—Despite the theory which indicates the employment of inhalations of compressed air, the facts are opposed to the treatment, and hæmoptyses are certainly to be feared.

Resume.—There is no precise indication, and there are everywhere contra-indications respecting the application of aërotherapy to diseases of the heart. It is a question yet to be decided, despite the rigor of the sphygmographic explorations of Franck and Riegel in their researches concerning the physiological effects of this respiratory method.

HEPATIC ALBUMINURIA.

By C. C. THAYER, M.D.,

CLIFTON SPRINGS, N. Y.

ALBUMINOUS urine always signifies a pathological condition. That pathological condition may be either within or without the kidneys; it may be entirely local, or may be general, and even in parts far remote from the kidneys. It may be inflammatory or mechanical, nervous, organic, or functional.

Traces of albumen in the urine are far from being a strange phenomenon. In fact, it is much easier to *discover* albumen in the urine, than accurately to define its pathological condition, or to declare its significance when found.

In the year 1827, when Dr. Richard Bright published his "Medical Reports" on albuminuria, the popular mind naturally drifted, as it was led thereby, to consider albumen in the urine to indicate definite pathological changes in the kidneys; and while we cannot justly say that this distinguished physician unequivocally declared that albumen in the urine was an *infallible* sign of renal disease, yet in his enthusiasm he pressed this feature, not too far, but to the exclusion in a great degree of other and equally legitimate phases of the same phenomenon.

These researches and reports rekindled and intensified a deep and wide-spread investigation into the significance of albuminous urine.

Christison, Osborn, and others indorsed, and further elaborated, the theories of Dr. Bright. Fourget reported albuminuria as dependent upon hypertrophy of the heart. Solon reported albuminuria as dependent on "obstruction of the circulation, peritonitis, crises of fevers, cutaneous affections, pregnancy, and pneumonia." Graves reported albuminuria as dependent on "chronic inflammation of the liver, phthisis, and diabetes" (Contributions to the Physiology and Pathology of the Circulation of the Blood," by George Robinson. London, 1857). The same author gives this proposition: "That the presence of albumen in the urine is produced by, and its proportional quantity is in direct ratio to, the degree of congestion of the capillaries of the kidneys, from whatever cause that congestion may arise" (Moreland).

Braun, Frische, Litzmann, reported albuminuria as dependent upon "mechanical pressure;" Rayer, Becquet, on "typhoid fever;" Copeland, on "powerful blood changes;" West, on "exanthemata;" Virchow, on "erysipelas." "It is known that the urine may become temporarily albuminous in consequence of an excess of albumen in the blood" (Dickinson, Wood's Library).

"These different views are not reconciled even at the present time; while many physicians to-day read the term albuminuria as an equivalent for kidney disease, there are others who attribute some, if not all, such cases to an altered condition of the blood" (Ziemssen's "Cyclopædia," vol. xv.).

As all renal diseases do not produce albuminous urine, so albuminous urine is not, *per se*, an evidence of renal disease. Among the varied pathological conditions outside the kidneys that give rise to albuminuria, my attention has been called of late to two cases, where daily examinations, careful investigations, and varied tests seemed to prove that the albuminuria (in said cases) was not produced by, or dependent on, any pathological changes in the kidneys themselves, but upon some gastric or hepatic disorders.

CASE I.—Mr. K——, merchant, aged twenty-four; nervous, bilious temperament, mentally depressed, constipated, voracious appetite, palpitation, throbbing of arteries, with daily excretions of albumen in the urine.

He was treated as follows: Hepatic stimulants, Turkish, salt, and electro-thermal baths; electricity applied to the hepatic region produced considerable pain. After one week's treatment, *some* specimens of urine exhibited a diminished amount of albumen; *others* remained the same.

After two weeks *some* specimens contained none, yet within twelve hours the usual amount would reappear. He was still eating enough for two well men. Diet was now cut down one-half, when a marked change in the urine appeared. Urea increased; lithates and albumen diminished. After two months, albumen could no longer be detected.

CASE II.—Mr. K——, aged thirty-five, of bilious temperament; yellowish, lead-colored, rough, and dry skin; poor appetite, constant bad taste in mouth; flatulence, and constipated from youth. For months has had no movements save by the use of extraneous means, and often goes a week without being able to secure a movement from the bowels. Great tenderness over the liver and epigastrium; subject to chills and often night-sweats, with much muscular pain, nervous prostration, and mental depression; urine scanty, high colored, of high specific gravity, and loaded with lithates; albumen constant and clearly marked. He gave up his business last October, and consulted Professor Timothy F. Allen, of New York, who treated him one month.

He then consulted Professor E. L. Keyes, who took charge of his case.

Was brought here in March following, with the above symptoms. He was put upon a relaxing and depletory treatment, Turkish and electro-chemical baths, alkaline salts, and amylaceous food, with colocynth and hydrargyrum pills sufficient to secure a movement from the bowels once in two days, with stimulating packs over stomach, bowels, and liver. In two weeks his skin and color began to clear up, and in three weeks there was not a trace of albumen in the urine; had gained several pounds of flesh, and walked around very well.

Now, while there has been constant and considerable albumen in the urine since October 1st—seven months—and we know not how long before, we have been unable to discover the slightest evidence of any structural changes in any of the renal organs. Where, then, must we look for the source of the albumen? Not in the nervous system, for they presented neither of the nervous conditions known to give rise to albuminous urine; not in any organic lesion of the heart, for they had none; not in any febrile condition that sometimes for a limited season produces albuminous urine; but we may look for it in line with their prominent and harmonious symptoms of gastric and hepatic disorders. We may search for the cause of *this* symptom where we look for the cause of their other symptoms. That the albumen is associated with, and dependent upon, hepatic and gastric disorders is incontrovertibly substantiated by the positive relief afforded by the hepatic and gastric treatment employed. This line of reasoning is abundantly established by Prout, Cohnheim, etc. Exactly *how* albuminous urine is produced in these cases is not yet clear, but the fact is authorized by Carpenter, Bennett, Dalton, and others. The same may be said of chyluria and glycosuria. "There are also reasons for believing that albuminous urine may be induced by hepatic derangements, independent of structural disease of the kidneys. I have met with several instances of hepatic colic, but where there was no jaundice, and the paroxysm was followed by a temporary increase of lithates and albuminous urine" (Murchison). Dr. Parkes ("On the Composition of the Urine") thinks, through some failure in the preparation, either by the stomach or liver, crude albumen is introduced into the circulation and excreted by the kidneys. Claude Bernard found that crude albumen injected into the jugular vein produced temporary albuminuria. "It is well known that if two or three raw eggs are eaten at once, albumen makes its appearance in the urine" (Fothergill).

This last quotation is in line with the above reasoning, but must be limited to cases of gastric and hepatic disorders; as experiments show that in such cases, and such only, does the eating of raw eggs produce albuminous urine. To test this truth I ate at one meal six rare-cooked eggs, and made a careful test of the urine at four and eight hours afterward. Then I ate at one meal twelve hard-boiled eggs, and tested as before. Then I ate at one meal six raw eggs—in all, twenty-four eggs in twenty-four hours, but not the slightest trace of albumen could be found. After repeated tests of this kind upon myself, and similar ones on others, I assume that albuminous urine cannot be produced where there is a healthy state of digestion with a free portal circulation; and had Claude Bernard injected crude albumen into the circulation on the other side of a healthy liver he would not have found it in the urine. Claude Bernard's experiment is valuable in the discussion of this subject, in that it shows that crude albumen may be excreted in the urine. And thus we are brought one step nearer to the solution of this question, namely: *that albuminoids passing through the digestive process, in excess of the powers of the liver to deal with them, may produce albuminous urine.* As an excess of lithates in the urine may indicate defective powers of the liver, instead of defective metamorphosis of tissue (for they have never been tissue), so albumen in the urine may indicate not a degeneration of tissue (for it never was tissue), but defective metabolism in "liver indigestion," and both are aborted proteids, wrecked on their way by defective digestion and assimilation.

A pertinent question here arises. What is the character of the albumen in hepatic albuminuria? Is it egg albumen (Fothergill)? is it globulin (Lehmenn)? is it a peptone (Lander-Brunton)? If it were egg albumen, it could be positively distinguished by the use of ether in the test. For while this secretion of the fowl's oviduct resembles albumen in the blood-serum, and while its action under heat and nitric acid is virtually the same, yet egg albumen is precipitated by ether, while the albumen of the blood-serum is not. If it were globulin, or "latent urine albumen," it could be shown by the use of alcohol in the test, but not by boiling or by nitric acid. If it were peptones, it would not be coagulated by heat or nitric acid in the test.

Traces of albumen in the urine are often unnoticed, because of imperfect examinations.

1. The test-tubes should be perfectly clean, else both the character and appearance of the urine may be changed.

2. The urine should always be rendered slightly acid by the addition of a few drops of dilute acetic acid, as albumen is held in solution in alkaline urine, notwithstanding the application of heat.

3. A few drops only of nitric acid should be used, as an excess of it redissolves albumen. Egg albumen is not redissolved, except in part, by an excess of acid.

4. Latent albumen (Gerhardt) is not discovered by heat or nitric acid, but is precipitated by alcohol.

5. Albuminose in the urine is not coagulated by ether, heat, or nitric acid, but only by the metallic salts and alcohol in excess.

6. Albumen in the urine, first rendered slightly acid, is readily discovered by the addition of a few drops of a solution of potassium ferrocyanide, one of the most delicate of tests.

From the above clinical cases, statistics, and considerations, we draw the following conclusions:

First.—Crude albumen in the circulation may be excreted as such by *healthy* kidneys.

Second.—Crude albumen in the circulation may arise from a retrograde metamorphosis of albuminoids in the process of digestion and assimilation from liver *disease.*

Third.—Crude albumen in the circulation may arise from a luxus consumption of albuminoids in excess of the capabilities of a *healthy* liver.

Fourth.—Crude albumen in the urine denotes that albuminose, in its hidden course to its legitimate and ultimate end, viz., fat and urea, has escaped its proper destiny as an aborted proteid.

Fifth.—Crude albumen in the circulation denotes not a defective metamorphosis of tissue, for it has never been tissue, but a defective metabolism in tissue construction.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 2, 1884.

THE BRITISH MEDICAL ASSOCIATION.

THE meeting of the British Medical Association this week, a cabled report of which we present in this issue, was a remarkably successful one, not only as to attendance, but as to the subjects of scientific interest which were discussed. In point of numbers and representative character, there is probably no scientific association in the world that is its equal. Its organization is so simple and withal so perfect that its membership embraces the leading and working men throughout the kingdom, and gives it a proportionate influence for good, not only with the medical profession, but the public at large. This latter effect is in no small degree due to definite and concerted action in all matters not only pertaining to advancement in medicine, but to everything scientific and sanitary which effects medical legislation. Hence the profession of that country naturally look to the Association for such expressions of opinion as shall be forcibly direct as well as widely representative.

It is a matter of great congratulation with its many friends that the Association is prospering from year to year, and that its actual membership reaches into the thousands. One reason for the latter is possibly that there is no other organization in the country which can claim to compete with it, and that it combines in its general branches every element for effective work, and focuses the united energies of the most progressive medical and surgical minds. The addresses—of which Dr. Redfern's, in the present issue, is a type—are, as a rule, models of their kind, showing much study, patient research, and wide grasp of the subjects treated. This is no more than could be expected considering the care with which the orators are selected, and the necessary incentive for the best efforts on the part of the gentlemen so honored. The section work is also carefully looked after, and not only are the topics for discussion systematically advertised in advance, but the proper men are duly selected to present them. This gives ample opportunity for due preparation, and naturally invests the scientific proceedings of the Association with proper interest. The addition of a new section, on therapeutics and pharmacology, is a notable feature of improvement, and gives an earnest of the intention of the members to devote themselves to the study of a branch of our science which has of late been too much neglected by progressive investigators. There is already promise of much good work in these branches, and the importance of the same in its general bearing upon the future progress of medicine was properly enforced by the remarks of the learned president of the Association in his annual address.

Probably nothing has shown the influence and power of such an Association more than its practical demonstration of the utility of systematizing a collective investigation of disease. By means of its extensive machinery and its perfect system of organization, it can command the means to an end which cannot be equalled by any similar body. The work already done has been highly satisfactory, and we opine that each successive year the elaborate report of the committee on the collective investigation will grow in importance, and increase in interest accordingly. At least, so far, it shows what can be done in a proper direction, and should encourage similar committees to surmount what are, after all, only ordinary obstacles.

In thus reviewing the work and influence of the British Medical Association, it behooves us to utilize, in behalf of our own National Association, the lessons which it teaches. In a general way this can be done with great profit to us. There are certain drawbacks, in regard to organization and representative character, which will however be next to impossible to surmount. Great Britain is, comparatively speaking, a small country, and concentration of medical talent within a reasonable area is not impossible. On the other hand, thousands of miles separate the members of the American Medical Association. There are here certain elements that militate against continuous annual attendance upon the meetings, which are very serious ones to consider. Hence it follows that a new set of members make up the majority of those in attendance at each session. Some attempt has been made to overcome this tendency by the biennial meeting at Washington, but even this latter city is by no means central in location, and cannot be reached by the larger number of delegates in the West and Far West without great expense and without serious loss of time. Again, the incentive which obtains with our British brethren, within their easy travelling distances, of being called in consultation, does not exist with the larger number of the best men so widely scattered over our vast territory. Hence the tendency is for the leading men in different parts to do their best work in their district societies, and as a rule leave the so-called parent association to take care of itself in its own way.

It can hardly be necessary, in view of the example set us by our cousins, to urge the necessity for a better programme for section work. It has become too much the fashion with chairmen of sections here to seek papers from such as may find it convenient to come, rather than from such as should feel it their duty to come and contribute what they can to the interests of the sessions. There was an exception to this rule in some of the sections which met this year in Washington, notably in that of the Section on Medicine, but not enough, generally, to give us very sanguine hopes for desirably radical departures.

But from all this it must be understood that our best men are not backward in doing their work to suit their own purposes. Their local and State societies absorb a great deal of this, but their best efforts are expressed in contribu-

tions to our leading medical journals, which are very properly recognized as the best media for rapid and extended communication with all the leading centres, and with large circles of appreciative readers. In respect to thus utilizing information from widely scattered regions, we certainly excel our cousins, and in no small degree offset the necessity of a national association for the distribution of intelligence such as they possess.

But, after all, how to practically overcome the peculiarly inherent difficulties in the organization and work of our own association is not an easy matter. The British example cannot be followed throughout, for reasons already suggested. Interpreting the signs of the times, we may say that the tendency in this country is toward State rather than National society work.

THE SCIENTIFIC GRANTS REPORTS OF THE BRITISH MEDICAL ASSOCIATION.

THE series of reports from committees to which sums of money had been granted by the British Medical Association begins this present year with the report of Mr. G. F. Dowdeswell, on the "Intimate Nature of Contagium in Certain Acute Infective Diseases." Mr. Dowdeswell prefaces his report with a review of the present status of scientific opinion as to the relations of micro-organisms and infective diseases.

There are now two distinct schools of schizomycologists: one, represented by Cohn, Koch, and others, uphold the doctrine that a difference of either form or function is sufficient to establish a distinct species, and that these different species are constant, and do not merge into each other. The other school, represented by Von Nägeli, Billroth, Lankester, and indirectly by Pasteur, contend that these different morphological and physiological forms are merely developmental phases of the varieties, brought about by external condition of a very few distinct species.

Mr. Dowdeswell's investigations relate largely to the above points. He examined experimentally into the relations of micro-organisms to Davaine's septicæmia, and Pasteur's so-called septicæmia, or infective peritonitis (also known as Koch's "malignant œdema"). We would remind our readers that the specific septicæmia of Davaine is that produced by the injection of putrid blood into the subcutaneous tissue of healthy animals. Mr. Dowdeswell's experiments showed that this infection is the result of the presence of a special pathogenic organism, resembling *b. subtilis*, that the disease is unquestionably a specific septicæmia, not a septic intoxication, and that by successive inoculations of the blood of one diseased animal into another, the *virulence of the blood is not increased.* This is in opposition to the views of Coze and Feltz, and of Davaine, and so far as it goes tends to show that micro-organisms do not change in physiological function.

Pasteur's septicæmia, or "infective peritonitis," is a disease produced by injecting putrid matter into the abdominal cavity. An inflammatory exudation results, containing numerous micro-organisms, and this exudation when inoculated in other animals produces serous effusion, septic intoxication, and death. Mr. Dowdeswell found as had Sanderson and Klein, that the injection of a germ-free chemical irritant into the abdominal cavity also excited similar infective peritonitis. The micro-organism developing in these cases had already been described by Koch, who called it the "bacillus œdematis," and states that it is to be found on wet soils and is a common saprophyte, appearing where decomposition takes place, like *bacterium termo.*

Mr. Dowdeswell's conclusion regarding infective peritonitis is that it is not a specific septicæmia, but rather a septic toxæmia in which the micro-organisms play a subordinate and probably mechanical part. There is no increase of virulence here either in successive inoculations.

It is difficult in the short space at our disposal to give any fuller account of the report. It contains much else that is instructive and suggestive, and shows its author to be a careful and judicious investigator. It is only to be regretted that the work was not pushed a little farther in the lines wherein it was begun.

The second report is that of Dr. George Thin, upon "Leprous Infiltration of the Epiglottis, and its Dependence on the Bacillus Lepræ." It can be disposed of very briefly. Dr. Thin believes, if we understand him correctly, that the *bacillus lepræ* is the pathogenetic agent of leprosy. He relates the history of a case, and shows specimens illustrative of the mode in which this parasite acts. Its special home is the lymph or white-blood corpuscles. It migrates with these, modifies their activity, causing absorption of fibrous tissue, production of tubercles, and a low grade of inflammation. We can hardly agree with Dr. Thin that sufficient data yet exist to enable us to say that the bacillus is the cause of leprosy. His contribution to this subject is, however, a most important one.

Dr. W. North makes a report upon the "Influence of Bodily Labor upon the Excretion of Nitrogen." His conclusions have already been published. They in the main corroborate those of Dr. Parkes, and disprove again the crude investigations of Flint, Jr., in the same direction. We must say of Dr. North, however, that his work is very blindly and unintelligibly reported in the *British Medical Journal.*

THE PATHOLOGY OF THE CERVICAL SYMPATHETIC.

DR. PAUL JULIUS MÖBIUS has written an elaborate monograph (published serially in the *Berliner Klinische Wochenschrift*) upon the pathology of the cervical sympathetic. This interesting but mysterious part of human anatomy has received a great deal of attention of late years, yet its exact relations and functions are still far from being satisfactorily made out. Dr. Möbius, besides giving a critical review of previous contributions, furnishes something new in the shape of a unique case of paralysis of the cervical sympathetic produced by a knife-stab. The sharp blade entered the right side of the neck just below the angle of the jaw, and apparently cut the sympathetic cord entirely in two. There was very little bleeding and the wound rapidly healed, but the patient soon discovered that there were various disturbances of function upon the right half of his face.

His right eye tired easily, and became suffused with tears; the pupil was smaller; the lid-fissure narrower; the ocular skin-reflex on the right side (*i.e.*, the widening

of the pupil on strong irritation of the skin of the neck) was absent, the right eye was more moist and more easily injected. The face was no redder or more congested or moist apparently upon the right side than upon the left; but slight irritations easily produced right-sided flushings and sweating. The temperature in the right external auditory meatus was higher than that in the left (36.5° C. to 35.6°).

The right musc. risor. Santor. and platysma were a little paretic, and the right angle of the mouth hung lower than the left. The heart's action appeared normal and the patient did not suffer from vertigo, tinnitus, headache, or sleeplessness. He did have at times a disagreeable sense of feeling the beating of his heart. Applications of electricity to the neck produced no change in any of these symptoms.

We have related the history of this case because it shows very typically most of the phenomena which occur in one-sided paralysis of the cervical sympathetic. Slightly different symptoms, or a difference in predominance of special symptoms, naturally occur according to the location of the lesion. We may, however, sum up those symptoms which have been found in the cases reported by Seeligmüller, Nicati, Eulenburg, Mitchell, and others, as follows: 1. Myosis is always present in the eye of the affected side. The pupil may be one-half or two-thirds smaller than that of the other eye. It responds to light and to accommodation, but its motion may be slower than normal. 2. Narrowing of the palpebral fissure through paralysis of the muscle of Müller is almost always observed, *i.e.*, in thirty-five out of thirty-nine cases. 3. Sinking in of the bulb occurs more rarely and is a later symptom. It is due to absorption of orbital fat, and to paralysis of Müller's muscle. The tension of the bulb sometimes becomes less and the cornea flattened. 4. There is, quite uniformly, an increased temperature and redness on the affected side of the face. Sometimes the affected half simply flushes very easily on the application of slight stimuli. A few cases have been reported by Nicati in which the blanched face and lowered temperature have occurred along with the eye-symptoms of paralysis. 5. A decreased sweating of the affected side often occurs. 6. Slight trophic changes may occur, the subcutaneous fat becoming absorbed, but it is doubtful if true atrophy ever takes place. In paralysis of the cervical sympathetic on one side the heart's action is not slowed, the thyroid gland is not enlarged, and there are no distinctive cerebral symptoms, such as might be expected to occur in a vaso-motor paralysis of those intracranial vessels supplied by the sympathetic.

Dr. Möbius confines his attention chiefly to the subject of sympathetic paralysis, and seems inclined to think that this includes most of the pathological disturbances of the nervous strands in question. Only thirteen cases of true sympathetic irritation are cited. In these there was widening of the pupil, moderate exophthalmus, and accommodation paresis, coolness of the face on the diseased side, and increased heart's action. Seeligmüller noted a flattening of the cheek and dilatation of the pupil in two cases.

Möbius very correctly excludes from the category of cervical sympathetic diseases, migraine, Basedow's disease, angina pectoris, and progressive unilateral atrophy of the face. It is to be hoped that our teachers and textbook writers will soon become sufficiently advanced in nervous pathology to follow Möbius' example.

THE INFLUENCE OF THE CHOLERA EPIDEMIC.

No one can doubt that the present epidemic of cholera will have, and indeed has already had, an immense influence for good in the sanitary education of the people. There is no one thing about which doctors disagree less than that of the relation of filth to cholera. And everything in the history of the present epidemic has tended to enforce the lesson of the great need of municipal and individual cleanliness. Without filth no cholera, is the motto which has been learned from the past, and which has for the last six weeks been steadily inculcated by medical authorities.

The result is that throughout Europe and the United States there has been an amount of municipal scrubbing which is quite unprecedented in summer history. For, since the cholera epidemic of 1866 and 1873, sanitary organizations have increased in number and effectiveness, while the people have been educated to a more intelligent idea of their functions and usefulness. There is no doubt that the extra cleanliness produced by the cholera scare will effect a saving of life from other filth diseases far in excess of the mortality from the cholera itself, unless indeed it should spread beyond all expectation.

There is no paradox, therefore, in saying that the cholera in France has a beneficent side, and will eventually save more lives than it destroys. We might even assert that cholera is a disease which the people cannot spare quite yet from the world. It is needed as an educator and as a prophylactic against typhoid, diphtheria, and the other diseases that proceed from municipal filthiness.

THE BATH IN MISSOURI.

Dr. W. E. Scott relates (*St. Louis Courier of Medicine*) the case of an old Missourian "who hadn't been wet all over since '63." Following up with inquiries this alarming suggestion of uncleanliness, Dr. Scott reaches the conclusion that there is not one-third of the people of Missouri who average one bath per month, and again "there are at least fifty per cent. who do not take a full bath from October till the month of May!" This condition of things is not, says Dr. Scott, peculiar to Missouri. In these days of "health hints," hygienic handbooks, and sanitary propagandism, it is rather startling to learn that in the very home of "Listerine" half the people do not bathe from fall to spring, while a certain limited number have not been wet all over since 1863!

Suicide of an Epileptic.—Medical men can appreciate the state of mind which had been reached by the young man who shot himself in this city last week. For a number of years he had suffered from epilepsy. He had been treated by several prominent physicians, but had got no better. He found himself, on the eve of marriage, a confirmed epileptic with no hope of improvement held out and so he killed himself.

News of the Week.

Yellow Fever is said to be increasing at Panama. It has also appeared at Sonora, Mexico, and is spreading rapidly.

An Honor to Dr. Husted.—At the Annual Commencement recently held at the Syracuse University, the honorary degree of LL.D. was conferred upon Dr. N. C. Husted, a well-known and esteemed physician of New York City.

Dr. E. W. Jenks was the recipient of a cordial reception by his medical brethren on the occasion of his return to Detroit. This high compliment was well deserved, and the profession of that city did itself credit in tendering it.

The Illinois State Board of Health is now engaged in revising the "Register of Physicians," preparatory to publication. Any changes or corrections should be promply sent to the Secretary. Lists of the officers of the medical societies in the State are also requested.

Annual Meeting of the National Board of Health.—The National Board of Health held its annual meeting on July 30th, and elected officers for the ensuing year as follows: *President*—Dr. James L. Cabell, of Virginia; *Vice-President*—Dr. Stephen Smith, of New York; *Secretary*—George E. Waring, Jr., of Rhode Island; additional members of the Executive Committee—the Hon. Thomas Simons, Department of Justice; Dr. Charles Smart, United States Army, and Dr. T. S. Verdi, of Washington. A resolution was adopted that in view of the possible invasion of the country by cholera, and of the existence of epidemics of other diseases, and in view of the duty imposed upon the Board by law to obtain information on all matters affecting the public health, the Executive Committee is directed to put on duty such members of the Board as in its judgment may be necessary. At its subsequent meeting the Executive Committee directed that the members of the Board be placed on duty for the investigation of all matters which, in their judgment, have a direct bearing on the question of cholera as a present menace to the public health, and epedemic of other diseases existing in the country. Congress having failed to make appropriation for the purpose, it is understood that such duty is to be done without compensation.

Texas Fever among Western Cattle.—A consignment of cattle from Indian Territory was received at Kansas City and kept in the stock yards in that city for some days. They were then shipped, part to Manhattan, part to Chicago. Of 200 sent to the former place over 30 died of what seems to be Texas fever. Of 500 sent to Chicago, a large number were attacked with the same disease, and the whole herd has been isolated and killed.

New Facts as to the Cause of Death by Chloroform.—Professor K. Winogradow has reported to *Wratsch* the discovery of peculiar changes in the nervous ganglia of the heart in a person who died from the effects of chloroform. He believes that they throw a new light upon the cause of death in these cases.

Honors to Medical Men.—Professor Le Fort and Dr. Dumontpallier, of Paris, and Professor Tourdes, of Nancy, have been given the cross of the Legion of Honor. Dr. Paul Flechsig has been made ordinary professor of Mental Diseases at Leipzig. Professor Longmore, of Netley, has just been elected corresponding member of the Académie de Médecine.

The most Unique Medical Journal at present published is probably *Le Journal Médical Quotidien*. It is published daily, as its name implies, at Paris. All the matter is written out in excellent script, and this is then lithographed. The journal is autographic, therefore.

The International Otological Congress.—We have received a copy of the programme of the Third International Otological Congress, which meets at Bâle, Switzerland, on September 1st to 4th, 1884. Dr. Alb. Burckhardt-Merian, President, is also chairman of the organization committee. A list of thirty-nine promised communications is given. We observe that no Americans and only one Englishman are among the contributors.

The Late Guiteau.—Dr. Michael J. Madigan has been attempting the fresh and always interesting task of proving Guiteau insane. Dr. Madigan announces himself to be a cerebro-physiologist, and is doubtless very competent to tell, all too briefly, what is the truth about Guiteau. We venture to suggest to him, however, that he has a singular ignorance of certain well-established logical methods, and that, for instance, he can never prove Guiteau insane by showing that the editor of this journal is "only a surgeon." For the rest, the single sensation, aside from weariness, which this young man's polemic excites is a wonder that at this late date the Guiteau question cannot be discussed without personalities and passion.

The Death of Professor Jäger, the distinguished ophthalmic surgeon, of Vienna, is announced.

The Treatment of Cholera at Marseilles and Toulon is about the same, according to the *Times* correspondent. In the first stage, twenty drops of laudanum are given with three grammes of ether, and ice in the mouth to stop the vomiting. In the second stage, from ten to fifteen grammes of acetate of ammonia, the same quantity of alcohol, and injections of morphia are given. If the patient has embarrassed breathing, oxygen is inhaled and the limbs are rubbed with turpentine. The third stage is the coffin.

Progress of the Cholera.—There seems to be no doubt that the violence of the cholera is abating at Marseilles and Toulon. The deaths, according to Consul Mason, have fallen at Marseilles from an average of sixty, previous to July 22d, to between twenty and thirty on July 30th. At Toulon the daily average has fallen from forty to fifteen. On the other hand, the epidemic has spread to numerous small places, about two thousand in all, in the country about Toulon and Marseilles, and has appeared in an active form at Aix-les-Bains and at Arles. The disease has also crossed the Italian boundary and appeared in several small towns and villages. Up to the present time there have been about two thousand three hundred deaths in France from cholera, according to an estimate of Mr. Harold Frederic, the *New York Times*

correspondent. This same correspondent has furnished a very clear and instructive account of the state of affairs in the cholera-stricken cities, and shows very clearly the intimate relation between cholera and filth.

Of Toulon, he writes: "The city itself is situated on a flat plain, four feet only above the level of a tideless sea. The consequences arising from imperfect drainage, with a natural want of slope, are that the sewers have only a fall of eighteen inches, so, with a sluggish movement, the filth of the town drops into an almost stagnant sea. What is worse is that at the points where these drains flow they are only covered with plank, and the filth, disgusting to the nose, impresses itself on the eyes. You not only then smell, but you see, the garbage of Toulon. Just fancy people living in this city, of quite eighty thousand inhabitants, without the faintest glimmer of common sense in regard to public hygiene! Toulon must be inhabited by people who utterly ignore every precaution which health requires. Their habits, both in their houses and in the public streets, are indescribably filthy. Toulon has always been a breeding-place of disease. Small-pox when it broke out in Toulon was always of a malignant type, and more difficult to stamp out than elsewhere."

The patients at the hospitals in Marseilles and Toulon are nearly all from the lower classes. At first nineteen-twentieths of the patients died; later, the mortality became less frightful.

Dr. Koch's Report to the German Government on the cholera epidemic in France was made July 5th. The disease, he says, is undoubtedly of Asiatic origin, and the milder form of the malady, spoken of by Toulon medical men, is nothing but severe cases of diarrhœa. But, in reality, writes Dr. Koch, the disease is of a very violent form, and is making rapid progress. In examining the bodies of some patients, he found the cholera-bacillus. The fact that hitherto the plague has not spread extensively in the neighborhood of Toulon is due, he thinks, to the hilly character of the region, which was also less rapidly and severely infected on the occasion of previous cholera epidemics there. Finally, Dr. Koch expresses his conviction, based on past experience, that the Asiatic cholera now raging in the South of France, will also extend itself to the Continent of Europe. Immediately on the arrival of the report at Berlin the various Federal Governments were requested to take the necessary preventive measures against the spread of the disease to Germany.

Dr. Koch's Lecture on Cholera at Lyons.—At the request of the Lyons authorities, Dr. Koch while in that city gave a free lecture on cholera. He showed specimens of the bacilli. They were, he said, favored in growth by alkalies and killed by acidity or dryness. Three hours of dryness he thought mortal to them. They were inoffensive in the lungs, and to be baleful should be carried into the stomach. Opium he thought the best for early treatment. A strong stimulant might be useful later, but he was not, he said, able to indicate one. Chloride of zinc, sulphate of iron, and even mercury, were not efficacious, but he thought carbolic acid was. Nevertheless, he often washed his hands in Van Sweiten's fluid, which contained a thousandth part of bichloride of mercury. When it was observed to him that the past immunity of Lyons from cholera was at variance with his theory of dryness, the climate being damp and the city on a tongue of land where the Rhône and Saône meet, he ventured to think that freedom from epidemic was probably due to the excellence of the sewers. At the same time he feared that Lyons was too near by rail to Marseilles and Toulon to be spared this time. Cholera rarely attacked those the coatings of whose stomach and intestines were healthy. There was no greater predisposing cause among the healthy than fear, which at once affected these organs. Scouring floors and furniture was not nearly so good a preservative as polishing and frequent dry rubbing.

A Hygienic Institute in Berlin.—It is proposed to found a Hygienic Institute in Berlin, in connection with the Berlin University. Professor Koch will be placed at its head.

The University of Heidelberg is about to celebrate its five hundredth anniversary. The Baden Parliament has voted $40,000 to meet the expenses of the occasion.

Cholera Cures.—Naturally, the appearance of the cholera in Europe has led to the revival of various specifics or specific methods for curing cholera. The first to be brought to notice was the use of oxygen by inhalation. It was speedily shown, however, that this agent did little or no good. M. Paul Bert has revived the claims as to the utility of copper as a prophylactic and curative agent. He has adduced fresh evidence, as he thinks, of its value. But with the memory of the death of M. Thuillier still fresh in mind, it will be hard to excite any confidence in the prophylactic value of this metal. Prof. S. Samuel, of Königsberg, Prussia, calls attention, in the *Berliner Klinischer Wochenschrift*, to a treatment of cholera recommended by him a year ago, viz., the subcutaneous injection of warm saline solutions. He admits that the circulatory apparatus in cholera is like a sieve, and that injections directly into the veins are soon lost; but by injections into the subcutaneous tissue of the arms and chest he claims to have obtained excellent results. He cites a case in which seven ounces of water, and subsequently four and a half ounces, were thus injected with success. The treatment by applying ice-bags to the spine, in order to stimulate (or relax) the ganglionic centres, has also been again brought up for discussion. No certain conclusions regarding this method have yet been reached. Among other "cholera cures" that are of more or less historic interest, are: the injection of quinine into the veins; the plugging of the anus; the actual cautery over the kidneys; and the administration of large doses of sugar (to affect endosmotic changes in the intestines); asafœtida, capsicum, calabar bean, quassite, berberine, naphtha, phosphorus, sulphur, and various antiseptics have been at different times recommended as useful in cholera. Finally, Dr. W. C. Seaman has recently advocated in *The Lancet* a return to the use of calomel in gr. x to gr. xx doses, with cold affusions and subsequent friction.

Dr. Kidd's Address on Obstetric Medicine, delivered before the British Medical Association, is unavoidably crowded out of the present issue, and will appear in our next.

Reports of Societies.

British Medical Association.

FIFTY-SECOND ANNUAL MEETING,

Held in Belfast, Ireland, Tuesday, Wednesday, Thursday, and Friday, July 29, 30, 31, and August 1, 1884.

(BY DIRECT CABLE TO THE MEDICAL RECORD.)

TUESDAY, JULY 29TH—FIRST DAY.

THE Council met at 2 P.M. The first general meeting was held at 3 P.M., the retiring president, DR. A. T. H. WATERS, of Liverpool, in the Chair.

The minutes of the previous meeting were next read, as already published, and confirmed.

REPORT OF COUNCIL.

MR. C. G. WHEELHOUSE, of Leeds, Chairman of the Council, spoke of the increase of membership during the past year, which was over one thousand. The total number was now nearly

TWELVE THOUSAND MEMBERS.

Very few members had died during the past year. The Association was now in a prosperous condition with

A SURPLUS IN THE TREASURY,

and was increasing in influence and in representative character. The report after some discussion was adopted.

Mr. C. MacNamara, of London, was then elected Treasurer of the Association; vice Mr. W. F. Wade, of Birmingham. Mr. Wade was thereupon elected Vice-President for life.

DR. MCVAIL made a motion to the effect that the travelling expenses of members of the Council be paid by the Association. A long discussion ensued in regard to the propriety of such a measure. It was contended that as each branch association now sends a member to the Council that the aggregate tax upon the Association would be large; especially would this be the case with members from the more distant parts of the kingdom. The pay system would be no extra inducement for attendance. The motion was finally lost.

FIRST DAY—TUESDAY—EVENING SESSION.

The Association was called to order in pursuance of previous adjournment.

ADDRESS OF RETIRING PRESIDENT.

The retiring President, DR. A. T. H. WATERS, of Liverpool, made a brief address. He spoke of the changes that had been made in the character of the Council, so that it had become more representative. He believed that this would tend to increase the prosperity of the Society. He congratulated the Association upon its continued growth and present flourishing condition. He referred briefly to the subject of the medical bill which had been before Parliament during its present session, and had been the subject of much sharp discussion. He lamented the fact that it had been withdrawn, and that the prospects for medical reform were again postponed. In conclusion, he thanked the Association for the honor it had paid him in electing him to the presidency.

A vote of thanks was then tendered the retiring president, carried unanimously, and Dr. Waters was elected Vice-President for life.

Dr. Waters then resigned the chair in favor of Dr. Cuming, President-elect, who delivered his

PRESIDENTIAL ADDRESS.

DR. CUMING gave a cordial welcome to the visiting members on behalf of the profession at Belfast. He expressed his thanks also for the honor paid in electing him to the presidency. He then said that the present epidemic of cholera in France naturally brought up the subject of the sanitation of cities, and of Belfast in particular. The sanitary condition of Belfast was excellent except that the sewage polluted the harbor to a somewhat dangerous extent.

The subject of

MICRO-ORGANISMS

and their relation to disease was next considered.

Dr. Cuming contended that minute organisms underwent changes in character as do other animal forms, and in that way very likely determined the character and extent of epidemics. The old term, "epidemic constitution," could be explained on this theory of the modified life of micro-organisms. But in addition to the influence of micro-organisms there is something in the human body which modifies vital phenomena, whether normal or abnormal, and this was the diathesis. That there was this peculiar modification of vital activity was abundantly shown, and the recent studies in scrofula and phthisis had still more strongly confirmed it.

The President then dwelt upon the advantages to be expected from the newly created

SECTION ON PHARMACOLOGY AND THERAPEUTICS.

Much progress was now being made in these branches, and much more could be expected. Medicine could never be cultivated in the same lines with the physical sciences. There are too many elements of uncertainty or too many complex factors. But in the great art of relieving and preventing suffering more and more was being accomplished, and the medical profession was every year becoming one of more dignity and usefulness.

At the close of the address various proposed amendments to the by-laws were discussed, but no important motion was carried.

The Association then adjourned for social reunion.

WEDNESDAY, JULY 30TH—SECOND DAY.

The meeting of the Council was held at 9.30 A.M.

Dr. Balthazar Foster was elected President of the Council, vice Mr. Wheelhouse. The latter gentleman was elected Vice-President of the Association for life.

The second general meeting was held at 11 A.M.

DR. LEWIS A. SAYRE, of New York, gave a demonstration of the application of the

PLASTER JACKET

in diseases of the spinal column. Dr. Sayre showed the

methods of applying the jacket, and asserted the advantages of it over later so-called improvements.

Dr. William M. Ord, of London, delivered the Address on Medicine. His subject was

SOME PERVERSIONS OF NUTRITION CAUSED BY THE NERVOUS SYSTEM.

Many observers of late years had been contributing evidence to show that the nervous centres have a remarkable power over the processes of nutrition. Charcot, Weber, and others had suggested that chronic rheumatic arthritis was a nervous disease. That the arthropathies in tabes dorsalis were produced by nervous influence there could be no doubt. The speaker suggested that in these cases there was probably some lesion in or near the anterior cornua. He related the history of a very interesting case of progressive muscular atrophy in which there was a joint lesion.

Dr. Ord referred to the changes in opinion which had taken place by reason of observations like the foregoing and a closer study of the nervous system. When Sir James Paget's book first appeared it was laid down that all general diseases were of blood origin. Now it could not be denied that this view must be greatly modified. He had noticed many illustrations of the reflex and direct influence of the nervous system upon nutrition. He had seen uterine congestion produce, reflexly, irritation of joints, and even rheumatic inflammation. On treating the womb these symptoms disappeared. The speaker also instanced cases of

URINARY PARAPLEGIA,

in which paralysis was produced reflexly by disease of the urinary organs. The influence of the nervous system upon secretion was undoubtedly a very marked one and showed itself in a variety of ways. Fetid breath might be the result of a secretory dystrophy or nutrition perversion. The influence which mental disturbances have upon the secretion of milk is familiar to every one. The nervous system regulated the destruction of sugar in the body, and not infrequently exhausted or perverted conditions of this system resulted in temporary "non-diabetic" glycosuria. As this often occurred in persons of a gouty tendency, Dr. Ord suggested the term

GOUT OF THE LIVER.

The speaker discussed the subject of the relations of myxœdema to the nervous system, and the probability that this too was a nervous disease. He referred to Kocher's views on the subject.

Dr. Ord made the original suggestion that the thyroid gland was a trophic organ, and, perhaps, ruled the nutrition of the nervous system in a measure.

He referred in graceful terms to the debt which was owed to Dr. Weir Mitchell, of Philadelphia, for his contributions to the subject of the nervous system and nutrition.

At the conclusion of the address, Dr. A. T. H. Waters moved that a vote of thanks be tendered the speaker.

The motion was seconded by Dr. Gairdner and unanimously carried.

After the transaction of some miscellaneous business the meeting adjourned for the day.

REPORTS OF SECTIONS.

SECTION ON SURGERY.

Wednesday, July 30th—Second Day.

The Section on Surgery was called to order at 2 P.M. by Sir William MacCormac, President, who delivered an address

ON ABDOMINAL SURGERY,

in which he reviewed the advances made in that department during the past few years. Every part of heretofore forbidden ground had been boldly and successfully attacked by the surgeon, and visceral surgery had enlarged its domain of applicability beyond the most sanguine expectations of the most progressive of our forefathers. He particularly referred to gastrostomy as an operation which had for itself a brilliant future in properly selected cases. The radical cure of hernia was another topic dwelt upon by the speaker, who cursorily considered the different operations and the indications for their performances. The removal of the thyroid gland also claimed attention as a feasible operation in many cases heretofore allowed to drift along unrelieved.

Following the address was the discussion on

THE PLASTER-OF-PARIS JACKET IN THE TREATMENT OF SPINAL DISEASES,

opened by Dr. L. A. Sayre, of New York. The speaker demonstrated the principles upon which the jacket was applied, and referred in a general way to its superiority over other methods of fixation. Several additional points as to detail of application, were brought out in a general discussion which followed. His remarks were well received and becomingly appreciated.

SECTION ON MEDICINE.

Wednesday, July 30th—Second Day.

The Section was called to order by the President, Dr. J. W. T. Smith, of Belfast, who delivered an address.

The subject for discussion was

ALBUMINURIA, ITS CAUSES, CONSEQUENCES, DIAGNOSIS, AND TREATMENT,

which was opened by Dr. George Johnson, of London. He reviewed the subject in an exhaustive manner, noting all the more recent advances made in its study, particularly those referring to diagnosis and treatment.

In the discussion which followed, a letter was presented from Sir Andrew Clark, of London, calling attention to the importance of recognizing the non-functional forms of albuminuria. These he thought should be divided into four varieties, hepatic, oxaluric, gouty, and nervous.

ADDRESSES BEFORE THE SECTIONS.

The other addresses before the Sections this afternoon were respectively as follows: "Obstetric Medicine," by Dr. Clement Godson, of London; "Ophthalmology," by Dr. W. A. McKeon, of Belfast; "Physiology and Pathology," by Dr. W. S. Greenfield, of Edinburgh; "Pharmacology and Therapeutics," by Dr. Thomas J. Maclagan, of London.

In the evening a conversazione was given to the members of the Association in Queen's College by the President and Executive Committee. This was largely attended.

(To be continued.)

THE MEDICAL SOCIETY OF BERLIN.

Stated Meeting, June 25, 1884.

HERR SENATOR, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society having been called to order, HERR SCHÖLER exhibited a case of

MARKED RETRACTION OF THE CONJUNCTIVA.

The patient, a woman, sixty-nine years of age, had been in excellent health up to within about three years. Since 1881 she had had two attacks of pneumonia, and it was at one time feared that she was developing a pulmonary tuberculosis, but this danger was now past. In February of this year she had what appeared to be a simple catarrhal conjunctivitis, for the relief of which ordinary astringent lotions were employed. The swelling and redness did not subside, however, and in May the patient applied to Herr Schöler. He found the conjunctiva in both eyes evenly suffused, with here and there little specks of thickened secretion. There was, further, a very marked contraction of the fold where the conjunctiva is reflected from the ball of the eye to the lids. At that time the contraction of the superior fold was not so great but that the upper lid could be everted, but now it was as far advanced as at the inferior fold. Cicatrix-like bands could be seen, but there were no adhesions.

The patient gave no history of any former affection of the conjunctiva, and there was no disease of the eye itself. The cornea was perfectly normal. The speaker said that there were but two recognized conditions in which such an extensive retraction of the conjunctiva could occur. The first of these was granulation. But when this process has advanced far enough to cause such an atrophy of the conjunctiva, we always find corneal opacities. The second was pemphigus; but here, also, the cornea is always involved. But one similar case has been recorded, the account of which was published by Alfred Graefe's assistant in Halle. Graefe gave to the affection the name of essential retraction of the conjunctiva.

HERR KÖBNER then presented a patient suffering from

LICHEN RUBER PLANUS,

affecting not only the skin but also the mucous membrane of the mouth and tongue. The patient, a woman, sixty years of age, had had a hard chancre three years before, but had never exhibited any secondary symptoms. Two months ago the patient noticed a number of little pimples, looking like gnat-bites, on both hands. These itched and burned considerably, and soon spread to the extensor surfaces of the lower part of the forearms. At the same time it was stated that her tongue was coated. The eruption now was thickly spread over the extensor surfaces of both hands and forearms, with isolated nodules on the soles of the feet, the shoulders, and the palm of one hand. On both sides of the anterior portion of the back of the tongue was a row of dirty white, irregularly oval, roundish, or polygonal specks. There were a few very small nodules here and there, arranged in semicircular groups. On the inside of the right cheek there were numerous whitish specks, arranged in the form of a network, and some similar growths on the red border of the lower lip. The patient had taken about half an ounce of iodide of potassium without effect, but had appeared to improve somewhat since the administration of small doses of arsenic.

HERR VIRCHOW read a paper entitled

SYPHILITIC JOINT DISEASES.

He said his communication occupied nearly the same ground which was gone over by Herr Güterbock in his paper read at the meeting held on June 11th, but that he should not confine himself to the hereditary form. Syphilitic joint disease bore no slight resemblance to arthritis sicca, but in the syphilitic affection there was always an increase in the amount of the synovial fluid. The seat of the lesions is the same as it is in arthritis deformans. The principal changes take place in the cartilage, and consist in a gradual destruction of this tissue, sometimes advancing so far that the cartilage is entirely absent in certain portions. On the other hand, however, there is this difference between the two diseases, namely, that while in arthritis deformans the cartilage disappears and exposes the bone, in syphilitic arthritis the loss of substance in the cartilage is replaced by a coincident formation of connective tissue. In addition to this cicatrix-like development of connective tissue there is, in the worst cases, a villous growth, springing from the borders of these ulcers in the cartilage, and floating free in the fluid of the joint. One cannot help treating these lesions as though they were inflammatory, although they appear to be atrophic. The new growth of connective tissue at the bottom of the erosions in the cartilage recalls the cicatricial contractions of syphilitic lesions in other parts of the body. The author had never had the opportunity to examine a case in the early stage of this disease, but he thought it not improbable that there were in the beginning gummy processes at the points where the above-described lesions were found. In looking at the articular surfaces one would almost believe that pieces of the cartilage had sprung loose, so sharply defined are the edges of the ulcerations. They are found usually in the central parts of the joint and not, as in arthritis deformans, around the outer surface. Any of the joints may be thus affected, and undoubtedly the disease may in certain cases progress so far that the whole of the articular cartilage may be destroyed. The author exhibited a number of specimens showing the changes described, and related briefly the histories of the cases from which they had been taken. And he concluded from a study of these cases that there existed a

CHRONIC ARTICULAR CHONDRITIS

of a syphilitic nature. This disease resembled most closely arthritis deformans, yet differed from it in some important points. In the latter there is a new growth of cartilage tissue about the edges of the bones, but no such change takes place in the syphilitic affection. The disease runs its course without suppuration, in which it differs from the other form of syphilitic arthritis, sometimes met with in adults, which is accompanied by suppuration and carries off the osseous structure.

HERR A. BAGINSKY related a case of the hereditary syphilitic joint affection, described by Güterbock at a previous meeting of the Society, which he had observed in a child thirteen weeks old. In addition to the arthritis the child had also a skin eruption and pseudo-paralysis of the arm. This

PSEUDO-PARALYSIS

is not a very rare condition. The speaker met with two or three such cases on an average every year. At first sight there appears to be a true paralysis, for the affected limbs hang perfectly motionless; but a more careful examination reveals the fact that we have to do with a very different affection. Both the diaphyses and epiphyses of the bones are thickened, and any movements of the affected articulations cause severe pain. The joints are swollen, and suppuration sometimes takes place. Not infrequently the articular extremities of the bones are destroyed, and a wobbly joint remains.

There is still another form of joint disease in young children, in which there is nothing to indicate that it is of a syphilitic nature, and which the speaker thought was to be explained on the theory of a late appearing

PUERPERAL INFECTION.

The affection is seen in children three or four weeks old. There is first infiltration and swelling about the joint, later suppuration in the joint itself, and finally per-

foration. Particles of bone and cartilage may even be extended through the opening, and yet the subsequent progress of the disease is favorable. In one such case that he had observed there was perfect restoration of joint motion, so that the child, after it had begun to walk, had not the slightest limp. As regards the

TREATMENT OF SYPHILITIC JOINT DISEASES,

he had for years made use of corrosive-sublimate baths, to the exclusion of all other therapeutic measures. He used seven and a half grains of bichloride of mercury for each bath, and gave a bath every day or every other day. Twenty such baths suffice to bring about a substantial improvement, or even a complete cure, in some of the most severe forms of infantile syphilis. There is no necessity for giving calomel or any other remedy internally, thus saving the stomach from possible injury, a matter of no small importance for syphilitic children.

HERR HENOCH said that the director of the children's clinic in Naples had recently sent him his work on the joint diseases in hereditary syphilis, in which he found six cases of the affection described by Güterbock. It seemed to him, however, that there might be some doubt as to the syphilitic nature of all the cases there given. It was possible for other joint diseases to occur in syphilitic individuals. He could not understand how it was, if these affections were so common, that there was so little opportunity to observe them in Berlin. Of the immense number of children treated by him for hereditary syphilis, he had never yet seen one with syphilitic joint disease. It was true that he had had one patient who had at the same time arthritis of the elbow and syphilis; but while the other symptoms disappeared during a course of specific treatment, the joint disease steadily progressed. He therefore thought it fair to assume that the arthritis was non-specific in character.

HERR HIRSCHBERG asserted that he had often seen the joint affection of hereditary syphilis. At the same time with the characteristic deformity of the teeth, there was hydrarthrus of the knee. This was regarded, not only by the Germans but also by English authors, as a specific affection.

HERR HENOCH maintained that this malformation of the teeth was no indication of syphilis, for it was often observed in healthy children, and was as frequently absent in those who were undoubtedly syphilitic.

HERR HIRSCHBERG had convinced himself that Hutchinson's assertion on this point was correct. All syphilitic children might not have misshapen teeth, yet when the dental deformity existed, it was a certain indication of hereditary syphilis.

HERR G. LEWIN agreed with Herr Henoch. He thought the malformation of the teeth was due to nutritive disturbances rather than to syphilis. Referring to Herr Virchow's paper, he asked if the lesions there described were not the same as those occurring in caries sicca. He was inclined to believe that they were. The speaker then related some cases, occurring in his practice, of syphilitic arthritis in both adults and children.

HERR SCHÖLER held to the views advanced by Herr Hirschberg. He related an instance of joint disease in a child which had yielded readily to specific treatment.

HERR SONNENBURG was in accord with Herr Henoch in the opinion that syphilitic arthritis was a very rare affection. He had met with but two cases in his clinic in a number of years. He considered it exceedingly difficult to diagnose these affections, since there were no characteristic symptoms. He had seen a number of cases of joint disease in syphilitic children, but they resisted all specific treatment, and he had his doubts as to their syphilitic nature.

On motion it was resolved to postpone further discussion until the next meeting, and the Society then adjourned.

SUGAR-CURED is the epithet applied by *Puck* to the successful results of homœopathic medication.

THE HOSPITALS MEDICAL SOCIETY OF PARIS.

Stated Meeting, June 27, 1884.

M. BUCQUOY, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society having been called to order, the President announced the death of M. Moreau, of Tours, at the age of eighty-one years.

A somewhat heated discussion, participated in by a number of the members, then followed upon the question of establishing a

STANDING COMMITTEE ON EPIDEMICS.

It was finally decided to create such a committee, and the President appointed MM. Vallin, Bucquoy, Danlos, Du Castel, Labric, Laveran, and Tapret.

M. CADET DE GASSICOURT presented the third volume of his

TREATISE ON THE DISEASES OF CHILDREN.

He desired to call the attention of the members especially to the chapters on meningitis and diphtheria, two subjects to which he had devoted considerable study. He had been able, by the study of ten thousand cases seen by himself, to correct certain statements made by different authors concerning diphtheria.

M. TENNESON then exhibited a

PORTE-OUATE,

or cotton-holder, for making local applications to the cavity of the uterus. It consisted of a sound which could be bent in any desired curve, the end of which was provided with a little wad of cotton. The cotton could then be dipped in any medicinal substance and carried into the uterine cavity without necessitating a previous dilatation of the os.

By means of this instrument M. Tenneson had obtained good results in the

TREATMENT OF CHRONIC METRITIS.

The local treatment of this disease, he maintained, should not consist merely in the cauterization of that part of the uterus which could be reached through a speculum, for cervical metritis is a very rare condition. Intra-uterine injections may cause death, and the introduction of a suppository, to be left in the cavity of the uterus, is very apt to give rise to an excruciating colic. The speaker thought his method of making applications was superior to all others. He used an ointment of sulphate of copper (five to eight parts in thirty) or of white precipitate (two parts in thirty) in preference to tincture of iodine, nitric acid, or chloride of iron. There were two contra-indications to this mode of treatment of chronic metritis. The first of these was perimetritis. In the case of peri-uterine inflammation there was danger of exciting suppuration in cauterizing the mucous membrane. It was also necessary to omit the intra-uterine applications during the periods of acute exacerbation which occur so frequently in the course of chronic metritis. Emollients are called for during such attacks, and the caustic applications should not be resumed until the hypogastric tenderness has entirely disappeared, and the uterus is freely movable without pain.

M. MARTINEAU thought there was one fatal defect in M. Tenneson's instrument—a defect common to all similar appliances—and that was that the cotton on the end of the sound was not covered. In its passage through the internal os, the ointment would almost surely be rubbed off, and thus the attempt to cauterize the mucous membrane of the body of the uterus would miscarry. He had devised a porte-caustique, somewhat similar to Lallemant's instrument, by which the medicated cotton was retained within a canula until it was fairly within the internal os.

As regarded the treatment of metritis advanced by M. Tenneson, he thought it was very incomplete. He had seen four or five thousand cases of metritis in the past

six years, and he thought he knew something about the disease. The lymphatic spaces of the mucous membrane and parenchyma are the seat of inflammation. There are two lymphatic plexuses in the posterior part of the uterus, and it is there that the affection begins which is called perimetritis, or pelvic peritonitis, but which the speaker preferred to designate as

POSTERIOR ADENO-LYMPHANGITIS.

There is a deeply seated induration in this disease which no superficial applications can reach, but which can be removed only by stimulating the circulation in the part, and thus promoting the absorption of the exudation. Finally, it should be remembered that uterine inflammation is often dependent upon a diathesis, which latter is amenable to general treatment.

M. TENNESON preferred the term perimetritis as one not indicating a possibly erroneous pathological conception. He was prepared to admit, however, that the lymphatics played an important rôle in the production of the diseases, as M. Lucas-Championnière had pointed out. The speaker had not asserted that local treatment was sufficient, but had spoken of the general therapeutic management simply because that was not included in the scope of his communication. But he desired to protest against the idea of a diathesis. Diatheses were words, and nothing but words, used merely as a cloak for ignorance. He repudiated the term and the conception which was sought to be expressed by it.

M. MARTINEAU claimed that he was the first to demonstrate the part played by the lymphatics in perimetritis.

M. BUCQUOY thought the credit of priority was justly due M. Lucas-Championnière.

M. MARTINEAU admitted that others had spoken of lymphangitis in this connection, but he maintained that he had studied the subject more carefully than they.

M. DU CASTEL exhibited a specimen of

TUBERCULAR MENINGITIS

limited to the paracentral lobule. This was now the third case of this kind that he had seen, and he believed that this was the usual seat of localized tubercular meningitis in the adult.

M. BUCQUOY showed a patient who had suffered from an

HYDATID CYST AT THE BASE OF THE BRAIN.

He had related the history of this case at a former meeting of the Society, and some discussion had been aroused at the time. The patient was now perfectly well.

The Society, on motion, then adjourned.

A MEDICO-LEGAL NOTE.—A decision interesting to physicians, says the *Philadelphia Medical Times*, was recently rendered in the courts of one of the Western States. Two surgeons had been employed in a certain case, but in different ways and for different compensations. The patient did not seem satisfied with the treatment, and refused to pay either of the bills rendered. As a result, suit was shortly brought by one of the surgeons, and defended on the ground that the services were of no value. The court held, however, in favor of the surgeon, and judgment was given for him. This result was so unsatisfactory to the patient that he thereupon began a suit for malpractice, and one of the defences interposed was that this question had been, in effect, adjudicated in the previous suit and could not be again raised. This defence the court held to be a good one, deciding that the former suit was a bar to the second one. This decision is only one of several in the various States holding the same way, so that a physician or surgeon need not fear a direct suit for damages from malpractice if the value of his services have been acknowledged in a suit to recover the amount of his bill.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. HUTCHINSON'S LECTURES AT THE LONDON HOSPITAL—EARLY SYMPTOMS OF CANCER—MEDICAL MEN AND THE TEMPERANCE CONGRESS—DR. RICHARDSON ON PAINLESS SLAUGHTERING—THE NORTH LONDON CONSUMPTION HOSPITAL—CHOLERA AND PRECAUTIONS AGAINST IT—THEORIES OF THE DISEASE—SMALL-POX.

LONDON, July 12, 1884.

As Emeritus Professor, Professor of Clinical Surgery Mr. Hutchinson is now delivering his second annual course of lectures at the London Hospital. This course was instituted last year on the occasion of Mr. Hutchinson's retirement from the acting surgical staff, when he was appointed consulting surgeon. It was considered desirable to retain him as a teacher in connection with the Medical College, so he was made Emeritus Professor, and undertook to deliver six lectures annually on some subject connected with surgery.

The lectures for the present year are perhaps a greater success than those given last summer, and being wholly delivered extempore appeal more directly to the minds of the auditors. It goes without saying that Mr. Hutchinson gives no mere summary of ordinary text-book opinions, but lays before his hearers, in plain and unmistakable terms, the results of his own clinical experience.

On Wednesday, July 2d, a good audience assembled to hear the lecture on "The Early Recognition of Cancer." The term "cancer" was used in its clinical sense and as including sarcoma, and not in its limited anatomical sense applying solely to carcinomatous growths. The importance of its early recognition was obvious. Mr. Hutchinson said that before the actual presence of cancer was what might be termed the pre-cancerous stage, and this was essentially a condition manifested by signs of local inflammation. An interesting case was narrated in support of this view. It was that of an old gentleman whom Mr. Hutchinson saw in consultation some years ago. One testicle had enlarged and was slowly increasing in size. The surgeons who saw the case agreed that it was probably not malignant and recommended non-interference. It continued to grow, however, and was at last removed solely by request of the patient, who had all along been anxious about it lest it should be cancerous. It was examined microscopically and was found to be simply in a condition of inflammatory hyperplasia, and no signs whatever of malignancy were discoverable. The patient recovered from the operation, no further trouble manifested itself, and his medical attendants came to the conclusion that his testicle had been really unnecessarily removed. Two years elapsed. The remaining testicle then began to enlarge in the same way in which the other had done. Remembering the result of the previous operation, the surgeons strongly advised the patient against operation. As before, it continued to enlarge until finally it reached a considerable size. At last even the surgeon began to be alarmed and the patient's anxiety was extreme. The testicle was finally removed at the urgent request of the patient. It was examined and proved to contain a well-marked sarcomatous growth. The inference was that the one first removed would, if allowed to remain, have also acquired a sarcomatous structure, and that the inflammatory hyperplasia found was a condition leading up to that of actual malignancy.

Eczema of the nipple preceding cancer was an illustration. Mr. Hutchinson remarked that cancer attacked parts that were functionally dead, as the breast in women late in life. Among animals it attacked the cat, the dog, and the horse, but not the sheep. The two former animals led a lazy life and were allowed to drag out their

existence to old age. Sheep were usually killed before they were old enough to develop cancer.

The practical conclusion Mr. Hutchinson drew from his view was to treat as cancer all those cases where you suspected it—to adopt active measures at once and not wait for more decided symptoms until it might be too late.

The recent Temperance Congress at Liverpool had what may be termed its medical side. Several medical men took part in it and read papers and delivered speeches. Dr. Ridge, of Enfield, made some rather startling statements, which may prove of importance should further research confirm them. Dr. Ridge said he had been able to show by experiment that alcohol was injurious to the health of growing cells in direct proportion to the quantity to which the cells were exposed, and that even a single drop of alcohol in a quart of water was able to affect them injuriously under suitable conditions. He now announced that he had found that alcohol, while we knew it to be an antiseptic in large quantities, was really a septic agent in very small ones, and that it promoted decomposition of animal and vegetable matter with bacterian effects. The accompaniments, if not the causes, of its decomposition flourished and were propagated to a greater extent when minute quantities of alcohol were present than when the decomposition was going on entirely in its absence. Below one per cent. the amount of alcohol present affected in proportion to its amount the degree of decomposition. Dr. Ridge deduced from these facts an argument against moderate drinking.

At the annual meeting of the Society for the Prevention of Cruelty to Animals on Monday, July 7th, Dr. Richardson gave an interesting account of the researches he had made to discover the best method of slaughtering animals without pain. He said that he had come to the conclusion that the electric shock could not safely be made use of by those who have to put animals to death. He had made experiments with various anæsthetics, and had chiefly employed carbonic oxide gas charged with the vapor of chloroform. Dr. Richardson has been able to make experiments on a large scale at the Dogs' Home, Battersea. Several hundred dogs have been painlessly put to death under anæsthesia, and sheep have been also killed in the same manner. Dr. Richardson suggests that the method should be employed in the killing of animals used as food. Painless slaughtering has been advocated by him for years, and now that an easy method is within reach we may hope for its adoption.

Another inquiry into hospital management is now taking place. This time it is the North London Consumption Hospital. This hospital is a most useful institution, and has had a good many good men on its staff. It is satisfactory to find that the errors of the past are likely to be redeemed in the future.

It is reported that a case of cholera is on board a ship now expected at the port of Cardiff. The authorities are quite prepared, and will not, of couse, allow any case to be landed. At every port the sanitary authorities are on the look-out. The various hospital authorities are bestirring themselves. In view of the fact that the stress of the last severe epidemic fell upon the East End, and that thus the London Hospital received within its walls a large number of cholera patients, a meeting of the staff of that hospital is to be held at once to consider what arrangements should be made in case of another epidemic.

Considering the probability of an invasion of cholera, it seems a pity it was not put down as a subject for discussion at the approaching International Congress. Even if no definite rules as to treatment had been agreed upon, we might have acquired some more distinct notion of its nature from hearing the views of investigators of various countries. The water-carriage theory is mainly held in England, but few of our clinical teachers have had the opportunity of practically studying the disease. In India, on the other hand, where most of our medical officers have had cholera cases to deal with, a large number of them decry the water theory altogether. The opinions held here are mainly the result of the teaching of the late Dr. Farr. He was an ardent advocate of the water theory, and all facts supporting it were pushed forward in the Reports of the Registrar-General, then edited by him. Opposed facts received at least scant courtesy, and many accused him of systematically suppressing them. The opinion of the Indian observers seems at least to merit a better hearing than it has yet obtained.

Small-pox is still increasing. Some of the hospitals have, in consequence of the prevalence of the disease in their neighborhoods, forbidden in-patients from receiving visitors as usual.

OUR PARIS LETTER.

(From our Special Correspondent.)

ANÆSTHESIA IN CHILDREN — GERMAIN ON THE GERM THEORY—HIS OPPOSITION TO THE SAYRE PLASTER-OF-PARIS JACKET—A STRANGE CIRCUMSTANCE CONNECTED WITH AN EPIDEMIC OF MEASLES AT BOURG ARGENTAL —A WORM IN THE EAR—CHOLERA AT TOULON.

PARIS, July 9, 1884.

In a work just brought out by Dr. de Saint-Germain, he resumes his clinical lectures of the last twelve years on different points of infantile surgery which came under his observation at the Children's Hospital in Paris, of which he is surgeon. In his first lecture the author treats of surgical anæsthesia, in which he shows that children possess no greater immunity against chloroform than adults, although the idea is entertained by some writers, the risk being the same in both cases. Nevertheless, M. de Saint-Germain never hesitates to employ chloroform in a great number of cases, even when it appears useless, as in keratitis. He prefers general to local anæsthesia, even when the latter would appear to be indicated, as, for instance, in opening abscesses, in operations for ingrowing of nails, etc., the local anæsthesia being as painful as the operation itself. Moreover, in the case of children one would have to fear the reaction after the application of cold. He employs chloroform alone; and in more than ten thousand cases in which he practised chloroformization he never had a single death. During the administration of chloroform M. de Saint-Germain attends exclusively to the respiratory rhythm and neglects the pulse, which, he says, gives indications too late to be of any value. The heart, it is known, dies the last.

M. de Saint-Germain often employs the Listerian method of dressing wounds, but without the least enthusiasm, and he expresses himself to the effect that the great lesson given by Lister to surgeons was to teach them how they were to wash their hands. He has no faith in the germ theory as far as the dressing of wounds is concerned, the ancient methods appearing to him sufficient in the great majority of cases.

According to M. de Saint-Germain, children do not enjoy immunity even against cancer. This is more frequent in boys than in girls, from the fact that cancer of the testicle is met with rather frequently, whereas cancer of the ovary is very rare. The forms most frequently observed in children were: the encephaloid and the fungus hæmatodes, then in the order of frequency the scirrhous form, epithelioma, and finally myosarcoma. The organ most frequently affected with cancer is the eye, and the encephaloid form is the most frequent. It is primarily intra-ocular and begins either in the choroid or in the retina. The treatment consists in the extirpation of the eye as soon as the diagnosis is established; it is the only chance in favor of the patient, and yet, unfortunately, relapses are not rare. I may here mention that Dr. de Saint-Germain is vehemently opposed to Dr. Sayre's system of treatment of spinal deformities, the plaster jackets as recommended by that surgeon being, he con-

siders, not only useless in these cases, but positively injurious, particularly in Pott's disease.

Dr. Paul Dagand has just published a report of a strange circumstance connected with an epidemic of measles which prevailed at Bourg Argental, in the department of the Loire, a short time ago. He detected the presence of a large quantity of round worms which had been expelled from the stomach and bowels, sometimes numbering as many as fifty. In one case a worm made its exit through the ear. A case occurred in a child aged seven years, who was affected with the measles. The child had been complaining of severe pain in the ear. On examination the physician noticed something which to him looked like the remains of a worm, in which he was not mistaken, as on trying to extract the object, to his surprise he found after its removal that it was a worm. The worm measured about twelve centimetres in length and two millimetres in diameter. The child had passed five or six of these helminths by the mouth a few days previously, which were slightly thicker than that which was removed from the ear. According to Dr. Dagand, the worm probably passed up through the Eustachian tube and perforated the tympanum. The child, who was seen again a fortnight after the occurrence, was quite well, with only a slight diminution of hearing of the right ear, which was the one affected. In getting the child to blow with its nose closed, no communication was perceptible between it and the ear. The otorrhœa which existed for a few days after the expulsion of the worm had disappeared. This case was brought to the notice of the Medical Society as a curiosity by Dr. Championnière, who remarked that though the case was very interesting, yet it was not without precedents. In the article "Lombric," in the "Dictionnaire des Sciences Medicales," Dr. Davaine reports that Winslow discovered a worm in the Eustachian tube of a little girl on whom he had a post-mortem examination. One extremity of the worm was in the pharynx, while the other was entangled among the bones of the tympanum. Bruneau, of Amboise, reports another case in which the subject was a young woman, from whose ear he removed an entire worm. He reports also that other observers had detected worms in other parts of the body. For instance, Rodriguez and Vrayet each relates a case of worms having been extracted from the inner angle of the eye. Apropos of these cases, Dr. Championnière observes that the migratory worms should not be confounded with the larvæ of insects which have sometimes been discovered under the eyelids, in the frontal sinuses, in the ear, and in the nostrils, and which might have been taken for entozoa.

The cholera at Toulon, which, as you are aware, broke out about three weeks ago, is still raging with varying intensity in that town, and although at first the local medical men were undecided as to the true nature of the epidemic, they are now agreed that the malady is indubitably of the Asiatic type. Dr. Rochard, Inspector-General of the Naval Department, and Drs. Brouardel and Proust, members of the Council of Hygiene, were deputed to report on the nature of the epidemic. These gentlemen gave it as their opinion that the disease, whether imported or not, is unmistakably the Asiatic cholera, though in a very attenuated form. Dr. Fauvel, however, the President of the Consultative Council under the Minister of Commerce, and who never went to Toulon since the outbreak, is singular in his opinion that the disease is of the sporadic type. This opinion he expressed officially, not only in his report, but before the Academy of Medicine at the outbreak of the epidemic, and to which he still adheres, on the grounds that it is not nearly so virulent or fatal as the Asiatic cholera. Moreover, it is more localized, has no tendency to spread, and was produced by purely local conditions, which are of the most anti-hygienic character that could be imagined. However, the epidemic has spread to Marseilles, but Dr. Fauvel thinks that it will go no further. May his prediction be realized. Meanwhile the whole country is in a state of panic, and the process of disinfection of men and things and other sanitary measures are being actively carried out.

RATTLESNAKE POISONING IN NEW YORK.

To the Editor of The Medical Record.

Sir: The somewhat unusual occurrence in New York City of a case of rattlesnake poisoning, and its unfortunate fatal termination having furnished a popular theme for the daily papers, it may not be uninteresting from a medical standpoint to recite the history of another metropolitan case which occurred just two years ago, the full history of which was never published. At that time it was impressed upon me that there had been no cases in New York City for eighteen years previously, the victim then being, as were also the two recent cases, a showman. The occurrence of two cases in two years is hardly sufficient to make us apprehend an epidemic of snake-bites in New York, or, on the other hand, are the cases frequent enough to destroy interest in them as novelties in metropolitan practice. The history of the case I have to report is as follows: E. W——, aged thirty-two, a showman, entered Ward 9, Bellevue Hospital, July 10, 1882. As the proprietor of a menagerie and museum then exhibiting in the Bowery it was his custom every evening to study the habits of a collection of a dozen rattlesnakes he had confined in a cage. Being careless in the handling of one of the larger ones, it struck at his hand, severely wounding his thumb in several places. The wounds were deep and the fangs had full opportunity to exert their influence. He immediately commenced to suck the wound, and sent for whiskey. Before it arrived evidences of constitutional infection were apparent. He complained of fulness in the head, vertigo, impairment of vision, and great prostration. He drank copiously of the whiskey and continued to suck the wound. On entering the hospital, the hand and arm presented to us, who had never before seen a snake-bite, a most peculiar appearance. They were greatly swollen, hard and tense and had a strange mottled discoloration extending to the shoulder. The color was a yellowish green, and figured in a manner best described by the term mottled. He was delirious, undoubtedly in part due to the whiskey, the tongue was dry and brown, and he suffered greatly from thirst. He was in marked shock, verging on collapse, and for twenty-four hours it was doubtful if he would survive, but to the vigorous treatment employed I think his recovery can undoubtedly be ascribed. Moderately free incisions enlarged the wounds, and to these free applications were made of strong aqua ammonia, and into the hand, forearm, and arm a solution of carbonate of ammonium was injected. This was given for both its local and its constitutional effect. Poultices of flaxseed and charcoal, enveloping the entire limb were applied and frequently changed. Diaphoretic and diuretic mixtures were given, together with the joint administration of carbonate of ammonium and phenic acid, then under trial in the hospital. Just how much resulted from the use of the latter cannot with accuracy be estimated, but to the ammonium the major part of the credit is given. After a very critical stage of twenty-four hours he began to improve, and, barring a tedious convalescence, did well.

Gangrene of the thumb supervened, rendering necessary amputation. The mottled look of the limb remained for some weeks.

Another example of novelties in city practice are tarantula-bites, of which I have had two cases, both occurring in men engaged in unloading bananas from West India fruiters. The symptoms were similar in character to snake-bites, but much less severe in degree.

Fraser C. Fuller, M.D.

224 West Fifty-ninth Street,
July 15, 1884.

"Small Fevers Thankfully Received" is a motto suggested to a young physician by Dr. Holmes.

THE USE OF PEPTONIZED MILK, AND HOW TO MAKE IT.

To the Editor of The Medical Record.

Sir: A formula for a food, as well as for a medicine, will certainly disappoint one who wishes to try it, and it may do much harm, if it be wrongly stated. In my note to you on peptonizing milk, the word grains has in three places been printed grams or grammes, thus making the quantities fifteen times too much. The sentence, "Mix a powder consisting of five grammes of Fairchild's extractum pancreatis," etc., should be, "Mix a powder consisting of five grains," etc. In the letter from Professor Leeds, "1¼ grams of extractum pancreatis and 4 grammes of sodium bicarbonate," should read, "1¼ grains of extractum pancreatis and 4 grains of sodium bicarbonate." In justice to Professor Leeds as well as myself, please publish these corrections.

Yours truly, J. Lewis Smith, M.D.

New York, July 21, 1884.

A PROBLEM, ETHICAL AND MEDICO-LEGAL.

To the Editor of The Medical Record.

Sir: An unmarried woman, about forty-five years o age, of spare frame and delicate nervous organization, is now suffering, as she has formerly done after various intervals in her life, with hysteria, accompanied by some emotional and mental aberration, and exhibiting a tendency under her present management to confirmed insanity. Without medical advice or direction, her family have locked this poor woman up in a small room, have put strong and gloomy looking oak bars across the windows, have left her much of the time alone in the room, without a bed, chair, carpet, or show of comfort, having only an angular and uncomfortable lounge to lie on, and have provided her with no regular attendant, medicines, or physician. She has been sleepless, almost without appetite, and having a pulse of feverish and excited character. It is doubtful whether she has been provided with suitable and sufficient food. She has been treated to a strait-jacket several times, and the amateur directors of her case have sought diligently among the physicians of the town to have her bled freely, but none would do the job. In none of these attacks has she ever appeared dangerous, her most offensive freak (except some harsh talk about her relatives) consisting of a break for liberty, at night, perhaps not too well clad, and this not recently, but at one or two former periods, before this present demon-baiting system was adopted. The friends of this poor woman think themselves intelligent, liberal-minded, even benevolent. They are financially able to procure comforts and help for their afflicted relative.

Now for the

Problem.—What is the social and ethical duty and legal power of remedy in the above case, possessed by a neighbor and physician who knows and can prove facts as stated? Can it legally be that such neglect of skilled advice and treatment, and such an active course of mediæval or barbarous management be adopted and pursued upon the mere whim and guidance of unmedical and relentless friends (?) of the invalid? Has the educated and humane onlooker no power to interfere in the defence of outraged personal rights and for the correction of abused nature and health of mind and body? An early answer will oblige Humanity.

——, Pennsylvania, July 19, 1884.

[The law of Pennsylvania is that insane persons may be placed in a hospital: "On statement in writing of any respectable person that a certain person is insane and requires restraint, the judge shall appoint at once a commission to inquire into and report upon the case. This commission shall be composed of three persons, of whom one at least shall be a physician and another a lawyer. If after hearing the evidence they think it a suitable case for confinement, the judge shall issue his warrant for such disposition of the insane person as the circumstances of the case require. If any insane person is manifestly suffering from want of proper care, any law judge shall order him to be placed in some hospital for the insane. In such cases, however, notices must be served and a hearing given."

There seems to be a sufficient remedy indicated in the above.—Ed.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 20 to July 26, 1884.

Wright, J. P., Major and Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 89, par. 3, Headquarters Department of Texas, July 17, 1884.

Hartsuff, Albert, Major and Surgeon. Leave of absence extended one month. S. O. 79, Headquarters Division of the Missouri, July 18, 1884.

Reed, Walter, Captain and Assistant Surgeon. Relieved from duty at Fort Sidney, Neb., and ordered for duty as Post Surgeon, Fort Robinson, Neb., relieving Assistant Surgeon Henry McElderry, U. S. A. S. O. 62, par. 2, Headquarters Department of Platte, July 22, 1884.

Benham, R. B., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Brown, Texas. S. O. 90, par. 1, Headquarters Department of Texas, July 19, 1884.

Strong, Norton, First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, to take effect when relieved from duty in Department of the Platte. S. O. 68, par. 2, Headquarters Division of the Missouri, June 27, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending July 19, 1884.

Gihon, A. L., Medical Director. Ordered as Member of Board of Inspection.

Persons, R. C., Passed Assistant Surgeon. Ordered to U. S. S. Saratoga.

Seigfried, C. A., Passed Assistant Surgeon. Detached from U. S. S. Saratoga; ordered to Naval Hospital, Brooklyn.

Savre, J. S., Assistant Surgeon. Ordered to U. S. S. Independence.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 19, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
July 19, 1884	3	15	50	3	167	27	1	0
July 12, 1884	2	8	55	4	187	31	0	0
Deaths.								
July 19, 1884	1	5	11	3	30	16	0	0
July 12, 1884	0	3	14	3	27	18	0	0

Tubercle Bacilli in the Non-tuberculous.—Dr. George Zahn records at length a case in which tubercle bacilli were found in the sputa, but in which after death no tuberculous process at all was found in the lungs.

Alum coagulates the albumen of the saliva and mucus of the mouth into membrane-like flakes. It causes contraction of the capillaries, blanching of the mucous membrane, and subsequent diminution of secretion. Notwithstanding its power to coagulate albumen it is absorbed into the blood, and Orfila found it in the liver and urine. Circulating in the blood it contracts the capillaries, prevents the emigration of leucocytes and red corpuscles, and arrests secretion and hemorrhage. May it not also arrest cell-growth, and may not this harmless and not unpleasant remedy be tried against sarcomas, and even cancers of internal organs which cannot be reached by the surgeon's knife?

Acetum Opii is made from opium, ʒ v. ; nutmeg, ʒ j. ; sugar, ʒ viij. ; dilute acetic acid, O ij. This is the strongest liquid preparation of opium, viz., 75 grs. to ʒ j. or 6½ minims to gr. j. It is nearly free from the sickening smell of opium, and less apt to nauseate. The nutmeg helps to prevent nausea and there is almost complete absence of narcotine, the most irritating ingredient of opium to the stomach ; in this acetate equals deodorized opium. Dose 5 to 10 minims. It may also be given in aromatic vinegar, to make it still more pleasant and efficacious.

Apomorphia was discovered in 1869, by Gee. It results from the action of hydrochloric acid on morphia, which extracts one molecule of water. Codeia and hydrochloric acid makes chlorocodia, which splits into chloride of methyl and apomorphia ; sulphate of morphia with excess of sulphuric acid makes sulph-morphia and sulphate of apomorphia. *Apomorphia* is soluble in water, ether, benzol, or chloroform. Two grains injected into a dog causes vomiting, and coursing around the room in a curiously persistent and methodical manner. Cats do the same, and also turn summersaults in the air. Two grains more caused epileptiform convulsions ; and two more perfect relaxation and death. On man, one-fifth grain caused in twenty minutes headache, dizziness, oppression, and qualmishness ; face pale, free salivation ; pulse infrequent, small and feeble, and free vomiting in ten to twenty minutes. It is a cerebral emetic. Sometimes there is retching, at others free vomiting without effort. It is chiefly used hypodermically in cases of great emergency when it is necessary to cause vomiting. The dose is one-fiftieth to one-tenth grain. It has been used in some disorders of coördination, in sick headaches, disorders of the cerebellum, and in the early stages of cerebral meningitis. It is a dangerous remedy, and comparatively rarely used, although the homœopathists advertise it widely as a remedy against sea-sickness.

Ammonii Phosphas.—Phosphate of ammonia is made from dilute phosphoric acid, ʒ xx. ; aqua ammon. fort., q. s. It has a cooling, sharply saline taste, is insoluble in alcohol, but soluble in four parts of cold water. Dose, ten to twenty grains three times a day in water, or barley-water. It is supposed to make more soluble salts with uric acid than those of soda and lime, and to be useful in gouty concretions, gout, and rheumatic gout. In uric acid gravel it is more than rivalled by borax, the utility of which is very great. It enters the urine from the kidneys almost unchanged, attacks the uric acid, which it decomposes, forming a soluble urate of sodium. Dose five to thirty grains.

Ammonii Boras, or borate of ammonium, is made from one part of boracic acid in three parts of warm ammonia water. It has a strong ammoniacal odor, and dissolves in twelve parts of cold water. It is used for urinary disorders with an excess of acid or earthy phosphates, and in irritability of the bladder. It has fallen into disuse, but is nearly as useful as borate of sodium. Dose ten to twenty grains largely diluted. It of course is one of the remedies for lithæmia, and has been used in low fevers in the place of the carbonate of ammonia, especially when there is ulceration of the bowels.

Sugar as Food.—The *Deutsch-Amerikanische Apotheker Zeitung* (December 1, 1883), gives a note by Dr. Phipson, on sugar as a regular article of diet. Dr. Phipson opposes the general prejudice against sugar. He declares that he has, during forty years, eaten very largely of it, at least a quarter of a pound daily, not counting sugar-forming substances taken at the same time. During all this time he has not been under the necessity of taking medicine, and has not suffered from any complaint, except brief attacks which could be traced to irregularities in eating or in dress. He declares that the condition of men would be much improved if the use of sugar should substitute that of alcohol.

An Anti-rachitic Mixture.—Dr. Von Leser recommended, in a paper read before the Leipzig Medical Society, the following mixture in the treatment of rachitis :

℞.	Tinct. rhei vinos.....	20 parts.
	Solut. potas. acetici	10 "
	Vini stibiati.....	5 "
M.		

The beginning dose is five to ten drops three times daily. This is increased three drops every three days until twenty to thirty drops is reached. The maximum dose is continued three or four weeks. Improvement sets in so rapidly that this is then rapidly decreased.

The Cause of Objective Quacking Sounds in the Ear.—Dr. William S. Parker, of Piqua, O., recounts the following case and asks for a diagnosis : "Miss D——, aged thirty, about the last of October, 1883, had a slight fainting spell, not amounting to unconsciousness, accompanied with nausea and thickness of speech, so much so that she was unable to articulate. This lasted but an hour and a half, and was the only attack she ever had. I may mention that for several years she has been subject to very slight attacks of vertigo, which, but for the present state of affairs, would pass unnoticed. Since the attack in October she had constant ringing in the ears until January 1, 1884, at which time she noticed that the sound became interrupted in a manner hereafter described. I observe that she is in perfect health in every particular, and never had any serious illness. The ears are perfect, as is also their function. Upon examination at this date (June 12, 1884), I find by placing my ear against that of the patient, a distinct sound, precisely like that of the quacking of a mallard duck in the far-off distance (which she says exactly describes the sound as it seems to her). This sound is synchronous with each beat of the heart, and is heard very distinctly in the left ear, and only slightly less so in the right by myself, although the patient can only perceive it in the left ear. Pressure upon the carotids makes no difference in the sound. Inflation of the Eustachian tube also has no effect. Lying upon the left ear intensifies the sound very largely, says 'it is like the roaring of a saw-mill.' This condition has obtained since January 1st last, when it was first observed."

Removal of Benign Mammary Tumors without Mutilation.—Dr. N. E. Oliver, of Thornton, Ill., sends us the following : "In your issue of July 5th (Vol. xxvi., No. 1), on page 12, is an excerpt from *The Archives Med. Belges*, in which M. Molière claims originality for the (therein described) operation for the removal of (benign) mammary tumors without mutilation. Professor T. Gaillard Thomas, in a communication (read before the New York Obstetrical Society, February 21, 1882) to *The New York Medical Journal and Obstetrical Review* for April, 1882, describes the above operation as applicable to all benign tumors of medium size. It would seem that American medical literature scarcely receives appropriate recognition from our irascible French brethren, otherwise so distinguished a gentleman would not be guilty of so palpable a 'medical plagiarism,' or at any rate he would not be two years behind the times."

Trichinosis in Massachusetts.—Dr. Averill, of Campello, Mass., sends us the notes of several cases of trichinosis recently occurring in his practice. He writes: "On March 27, 1884, I was asked to visit a Swedish family consisting of husband, wife, and four children. I found husband and wife and eldest child (a son about eight eight years of age) all sick in bed, and learned that they all took to their beds about the same time some three or four days before calling for me. All had felt tired and languid for several days before taking to the bed. All were œdematous about the face and eyes, and the wife was markedly so all over her body. They complained of pains all through their bodies, headache, lassitude, muscles were sore and painful when touched or moved, limbs generally flexed, and extension caused extreme pain. The husband complained especially of pains across his thorax. Temperature about 102½°, pulse about 125." Dr. Averill learned that about a week before the sickness the family bought half a smoked ham, and all had been eating it raw except the three younger children, who were not attacked. Another family in the same house bought the other half of the ham. The husband alone ate some of it raw, and he alone was taken sick, but recovered. The three sick members of the first family gradually recovered, but it was about five weeks before the symptoms had disappeared.

The Lack of Progress of Cremation.—With reference to our recent editorial upon this subject, Dr. F. Hoffmann, editor of the *Pharmaceutische Rundschau*, calls our attention to an article by himself in the March number of that journal. He there shows by statistics the very slight progress that cremation as a mode of burial is making, and takes the ground that it is an uncalled-for and dangerous mortuary rite.

The Psycho-pathology of an Application for Increase of Pension.—A pension surgeon at Washington sends us the copy of a very ingenious medical certificate which was sent to his office a few days ago with an application for an increase of pension. "Affiants discover upon the right instep of the applicant a soft and movable cicatrix, as if the integuments had been ploughed up by a bullet. We find no deformity or displacement of the tarsal or metatarsal bones, and no erythema or hyperæsthesia of the surface of the wounded region. Affiants also discover that the applicant's disability is greatly increased at times by the reaction of the above described cicatrix on the higher nervous centres. We believe that a sensory impression, conveyed from the cicatrix through the second pair of cranial nerves, is intensified in the cerebrum by certain processes of intellection, one of which is known as expectant attention. The impression so intensified and modified is then reflected to the region where the trauma was sustained, and the applicant's sufferings are increased many fold. Under such circumstances, and at the time when these reflex nervous phenomena are manifested, we believe that the applicant's disability is extreme, and that an increase is urgently indicated as a therapeutic measure. ——, M.D., ——, M.D."

The Therapeutic Value of the Iron Albuminate in Anæmia.—Dr. Allan McLane Hamilton writes: "I have been in the habit for several years past of giving iron in combination with albumen to nervous patients whose powers of assimilation were so enfeebled that they were unable to take any of the preparations in ordinary use, even the most bland and non-irritating. Anæmic and hysterical women and those with idiosyncrasies often declare their unwillingness or inability to continue the iron, even in minute doses, and in such patients something must be found to take its place. In the year 1871 Diehl announced the discovery of the albuminate of iron, but so far as I can discover, no one has yet employed the combination in medicine. Miahle has held that 'the albuminate of the peroxide of iron is formed in the blood and that this is the basis of the red globules,' and it has been shown that the presence of an alkali favors the catalytic change. Some iron salts are absolutely inert as remedies and pass unaltered from the body. Among these are the ferro and ferricyanides of potassium and other double salts which are not precipitated by the alkalies (Headland). The combination of iron and albumen with an alkali seems to be at once a measure likely to be of value from a therapeutic point of view, and so I have found it. Mr. Theodore Angelo, of New York, has made for me a dry preparation of the iron albuminate, and he has combined with this chocolate and moulded this into small lozenges, each of which contains ten grains of the salt. I have given the iron albuminate a thorough trial in a large number of cases of all kinds where a hæmatic was needed, and am convinced that there is no form of iron now in use that acts as rapidly or is so well borne by the stomach as that of which I write."

A Question of Maternal Impression.—Dr. C. H. French, of Waterbury, Conn., writes: "I was engaged to attend Mrs. T—— during her confinement. Soon after conception a young man, whose right arm just above the elbow had been amputated some years ago, came to board in the family. Mrs. T—— felt very sorry for the young man, showing her sympathy by frequently washing and dressing the arm. She says that that young man's arm was seldom out of her mind, and that any person she saw who was similarly affected (she had seen several) sent a thrill of horror, followed by one of intense sympathy, through her. I delivered her, on June 5th, of twins. One of the children had the right arm just below the elbow missing. Whether this was merely a coincidence or the result of the mother's mind over the fœtal development I am not prepared to state. In view of the fact that cases of this nature, taken collectively, may be of value, I send you this."

Some Delusions in Medical Chemistry.—That colorless tincture of iodine has the chemical and medical properties of the tincture of iodine. That serum albumen is the only albuminous body to be tested for in the urine. That potassium chlorate yields oxygen to the blood (some recent experiments have made this not so improbable). That corrosive sublimate or potassium permanganate can be given with vegetable preparations.

Identity of Friedlander's Pneumonia Cocci with the Organisms of Salivary Septicæmia.—Dr. George M. Sternberg, U. S. A., sends us the following important communication: "I am induced by your remarks upon 'Micrococci under the Floor' (The Medical Record, June 28), to call your attention to the apparent morphological identity of Friedländer's micrococci of pneumonia and the micrococci from the blood of a rabbit inoculated with human saliva, shown in Fig. 1 of the plate which illustrates my paper on 'A Fatal Form of Septicæmia in the Rabbit,' etc. (published in 1881), a copy of which I send you by mail to-day. This morphological identity was recognized at once by Dr. Wm. Welch, of New York, when I called his attention to this figure, upon his visiting the biological laboratory at Johns Hopkins University not long since. As Dr. Welch has personally demonstrated the presence of Friedländer's (?) micrococcus in pneumonic sputum, his recognition of this morphological identity at once confirmed my own suspicions. I have not myself had an opportunity to examine pneumonic sputum since the announcement of Friedländer's discovery (?)."

Urinary Test Papers.—Messrs. Parke Davis & Co., of Detroit, have manufactured a very neat and convenient pocket case containing the various test papers for urinary analysis recommended by Dr. G. Oliver, of Harrowgate, Eng. (*Lancet*, February 3, 1884), and Dr. C. W. Purdy, of Chicago (*Jour. Amer. Med. Assoc.*, January 19, 1884). It is also supplied with test tubes, and dropper making the whole a very useful pocket companion for the general practitioner.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 26, No. 6 NEW YORK, AUGUST 9, 1884 Whole No. 718

Original Articles.

PUERPERAL FEVER,

BEING AN ADDRESS ON OBSTETRIC MEDICINE,

Delivered at the Fifty-second Annual Meeting of the British Medical Association, held in Belfast, 1884.

BY GEORGE H. KIDD, M.D. ED.; M.A.O., HON. CAUSA, DUBL.

FELLOW AND EX-PRESIDENT ROYAL COLLEGE OF SURGEONS, IRELAND; HONORARY FELLOW LONDON AND EDINBURGH OBSTETRICAL SOCIETIES; CORRESPONDING MEMBER OF THE GYNECOLOGICAL SOCIETIES OF BERLIN AND BOSTON; CONSULTANT AND EX-MASTER OF THE COOMBE LYING-IN HOSPITAL; CONSULTING OBSTETRIC SURGEON TO THE HOSPITALS OF THE HOUSE OF INDUSTRY; PRESIDENT OF THE OBSTETRIC SECTION OF THE IRISH ACADEMY OF MEDICINE.

(Special for THE MEDICAL RECORD.)

MEETINGS such as those of the great Association under whose auspices we are here assembled have always appeared to me as having their most useful function in presenting opportunities for reviewing the work we have been doing; estimating the value of the results attained; eliminating, so far as may be, the erroneous or defective; and so getting plainly before us certain standpoints from which further advances may be made. I propose, then, in endeavoring to accomplish the duty imposed on me by your Council when they selected me for the high and honorable office of delivering an address on obstetric medicine, to take Puerperal Fever as my subject, and to treat it in accordance with these principles. In selecting this subject I have been influenced not only by its importance—its vital importance—to one and all of us, but also by the great advances that have recently been made in our knowledge of its pathology, and in some measure perhaps by the feeling that in our enthusiastic pursuit of the new paths that have been opened to us we are in danger of losing the clue that is to lead us out of the labyrinth in which we have so long been wandering. I shall ask you to consider the disease mainly from a clinical point of view, referring to the laboratory experiments of scientists and pathologists to illustrate and explain the facts observed at the bedside, where alone disease can be studied. In doing this I shall not attempt to present any new or original doctrines. My task must be the more humble one of stating, with what clearness I may, the questions at issue, and the facts on which their solution must be founded, endeavoring to arrange and balance the evidence, so that its true value may be more fully apprehended.

Much of the difficulty that has always attended the study of this disease arises from the similarity of the symptoms during life and of the pathological appearances found after death in its various forms. Its dependence on the great act of childbirth, and the peculiar condition of the patient's system at this period, sufficiently account for this similarity. The enlarged and highly organized uterus suddenly emptied of its contents after violent muscular exertion, and becoming a mass of effete material, whose constituent elements have to be absorbed into the blood as a preliminary to their being eliminated from the system; the exposed state of its vessels; the torn and contused tissues; the great current of blood diverted from the course it has so long been pursuing; the altered condition of the fluid itself, and the highly strained nerve-tension—all tend to concentrate the diseased action of one set of organs, and to impress on it this similarity of development. The attempts, consequently, that have from the earliest times been made to differentiate the various forms of the disease, founded on its morbid anatomy and its symptoms, have failed to simplify its study or in any great degree elucidate its nature. A classification founded on the conditions under which the disease arises, and the nature of the exciting cause adopted by some writers, as by Barnes in modern times, has proved more useful and done more to promote accuracy. One founded on this principle will probably best serve the requirements of the present occasion.

A writer of the last century, Kirkland, upbraids his contemporaries with including "a thousand disorders" under the one head of puerperal fever. It requires but a very elementary knowledge of the subject to see that a large proportion of these disorders arise from traumatic causes. These, then, will constitute the first group I will ask you to consider, and perhaps not the least important, seeing that so much can be done for their prevention.

In tedious and difficult labors, more especially in first labors, the soft parts of the mother are liable to be injured at every stage—the cervix may be lacerated, the lips may be caught between the head of the child and the side of the pelvis and contused, the vaginal walls may be compressed till sloughing be induced, so as to lay open the bladder or the rectum, or both; the perineum may be torn, or some of the blood-vessels may be lacerated, and blood be effused into all the surrounding tissues, giving rise to hematoceles, more or less extensive; and yet, formidable as the enumeration seems, we all know that in the great majority of cases the reaction is moderate, the inflammation set up is localized, if the damage done be not excessive it is repaired, and the patient recovers. But if the patient be in an unhealthy condition, or if her surroundings be unwholesome, then a new train of symptoms may arise, not necessarily depending on the extent or gravity of the wounds, but influenced by them. The inflammation, instead of being normal in character, becomes abnormal; it may extend to surrounding parts, and peritonitis or pelvic cellulitis may be set up; or more distant parts may be affected, and the disease will manifest itself in the pleura or the serous membranes of the heart or of the joints; or the blood in the veins may be coagulated, giving rise to thrombi and emboli, and subsequently pyæmia.

We have now to inquire what is the nature of this change. The researches of modern pathologists and scientists have proved that it is due to the introduction of a poison into the system, and that certain vegetable organisms (bacteria) are essential agents in the production and dissemination of this poison. They are not agreed, however, as to the exact part played by these organisms. Some hold that the most severe injuries may be inflicted without producing inflammation, and that when inflammation takes its origin from a wound, all that the wound does is to play the part of the door of entrance for the real *noxa*—water germ, air germ, or germ which sticks to the surface of the weapon or missile which inflicts the injury. They assert that in the genesis of every inflammation, however definite may be the relation between the antecedent damage and consequent reaction, this relation is after all merely secondary. The true cause is the introduction into the damaged tissue from

the atmosphere of invisible germs. Where there are no germs, there is no possibility of inflammation. Others, as Dr. J. Burdon-Sanderson, to whom we are indebted for most of our exact knowledge on the subject, teach that inflammation is the direct physiological effect of injury, and that the only inflammations to which minute organisms stand in relation are those which from their proved dependence on previously existing inflammation may properly be termed secondary or infective, and that consequently the organisms in question were in all probability not so much mischief-makers as mischief-spreaders —that is to say, although an inflammation may come into existence without their aid, their presence communicates to it, after it has come into existence, the power of reproducing itself in previously healthy tissues, whether by extension or dissemination. During the ten years which have elapsed since 1872 (when he first taught this), Dr. Sanderson says the question of the intervention of micrococci, which was then strange even to professed pathologists, has become familiar to everyone, and now the tendency exists to believe that germs explain everything; so that whereas formerly one had to vindicate the very existence of such things as parts of pathological processes, it has now become a part of one's business to protest with all needful vehemence against the attribution to them of functions they do not possess.[1]

In support of his theory he proves a series of propositions on an experimental basis that seem to leave no room for rational doubt. He shows that the introduction into the circulating blood of a relatively large quantity of exudation, which is the most important effect of a considerable local inflammation, does not produce secondary inflammation elsewhere, and is not attended with any serious constitutional disturbance. He further shows that no organisms endowed with inflammation-producing phlogogenic particles exist in the atmosphere or in the ordinary aqueous liquids with which our bodies come into contact.

It had been proved by Hiller that bacteria collected from fluids in an advanced state of putrefaction might, when washed and purified, be introduced into the circulating blood without producing any injurious effect, though proved to be as lively and capable of development as ever. Hiller[2] even inoculated himself with them. Dr. Wegner[3] showed that the subcutaneous tissue of a rabbit may be kept distended for days by frequently renewed injections of unpurified air without producing inflammation, and that the effect was not more serious if the same tissue were ventilated for a number of hours by a continuous current of air, even when that air was derived from a post-mortem theatre. When water charged with septic bacteria was injected into the peritoneum of a rabbit, in quantity less than two ounces, it produced no effect whatever. When the animal was killed, the fluid had been absorbed and the lymphatics of the diaphragm were full of bacteria, but neither in them nor in the peritoneum were there any signs of inflammation. Similarly it was found, that when a current of the fluid was passed through the peritoneum for many hours, so that the membrane was exposed for a long time to whatever phlogogenic influences the liquid conveyed, no effect whatever was produced. These experiments with watery liquids are even more conclusive than those with air, for we have here to deal with media, in every particle of which we can very readily prove the actual existence of germs in such a state of viability as to only require a suitable soil to insure their development.

Having thus proved that the exudation of a normal inflammation is not infective, and that no organisms endowed with inflammation-producing phlogogenic particles exist in the atmosphere or in the ordinary aqueous liquids with which our bodies come into contact, Dr. Sanderson proceeds to show that whenever an inflammation becomes infective it owes that property to a chemical change in the exudation liquid, of which the presence of microzymes is a necessary condition, and that conversely septic organisms, which are infectious, owe their infectiveness to the exudation soil in which they have grown. He refers to experiments he made a dozen years ago, which showed that in rodent animals peritonitis induced by the injection of irritant liquids is always infective, notwithstanding that the irritant (tincture of iodine) was not only free from germs, but destructive of them. This was, he says, understood to mean that the first effect of the iodine was the effusion of liquid into the peritoneal cavity; the second the infection of this liquid by formed ferments which found their way into it, not from the atmosphere or from external media of any kind, but from the alimentary canal. In another experiment, water which had been boiled so as to remove all germs that might have been in it, was, when cool, injected, with antiseptic precautions, in so large a quantity that it could not be rapidly absorbed. When thus accumulated in the serous cavity it charged itself by diffusion, first with the salts, subsequently in increasing proportion with the proteids of the blood, and thus became a most favorable soil for the development of septic organisms, which in their turn acted infectively or phlogogenically on the blood-vessels and living tissues with which they came in contact. A septic peritonitis ensued, which killed the animal by septicæmia in twenty-four or thirty-six hours. It is thus shown that though the seed is indispensable to the coming into existence of the infective process, the question whether that seed becomes morbific or not depends not on the seed itself, but on the soil. Other experiments prove the same thing, and the whole result is to establish that the presence of septic organisms (provided that they have not been bred inside the organism) is not necessarily attended with any danger, but that they become sources of danger at once when they are brought into relation either with devitalized organs or with extravasated serous fluids of any kind, and particularly with inflammatory exudation.

The sum of our knowledge of these organisms seems to be this: They are found everywhere—in the air, in water, in the soil; in the bodies of the most healthy animals, on the surface where most exposed to the air; in the entrances to the alimentary and air passages; in the stomach and upper portions of the alimentary canal, but not frequently here, for acid secretions kill them; in the lower portions of the canal frequently; possibly also in the tissues of solid organs, as in the pancreas, liver, kidney, muscle, but this is still a disputed question. In the circulating blood of healthy animals they are never found. They enter the system by the absorbents of the mucous membrane of the small intestines, the lacteals, by the pulmonary mucous membrane, by recent wounds, by the uterine surface after delivery. They exist in the animal body without interfering with health. If they meet with a proper soil, such as exudation liquid, or dead tissue, they set up putrefaction, and in the process of putrefaction a poison is produced which, mingling with the blood, poisons it and gives rise to septicæmia. This poison they carry into the system, but the bacteria themselves are not poisonous.

Thus, then, we must have two factors for the production of the poison—(1) The material capable of putrefaction; and (2) bacteria to effect putrefaction.

Now, how are we to apply this to our subject? It is well known, as Billroth remarks, that in most open wounds, especially in contused wounds, shreds of connective tissue die, and in many spontaneous inflammations the circulation ceases in some parts of the inflamed tissues and they die. Here, then, we have the material from which the poison is to be elaborated, and the inference is plain that the first step to be taken to avoid this form of puerperal fever is to so conduct the labor as to

[1] Lumleian Lectures on Inflammation. Delivered before the Royal College of Physicians. By J. Burdon-Sanderson, M.D., etc. Brit. Med. Journal, April 8, 1882, p. 593.
[2] Brit. Med. Jour., January 5, 1878, p. 2. [3] Ibid., April 15, 1882, p. 527.

lessen the amount of injury done, to be careful that the membranes be not ruptured too soon, and that the head be not allowed to press so long on the soft parts as to injure them, and above all that no violence be used.

In the second place, to cut off so far as possible the access of bacteria to the injured parts, by cleanliness, by ventilation, by disinfection; but the experiments of Chauveau and of Kocher, of Berne and of Sanderson, prove that even where all access of organisms from without is cut off they will pass from the intestinal canal or other sources to the point where dead or dying tissue exists, and there set up putrefaction and the elaboration of the septic poison, and consequently a third indication remains of equal, if not greater, importance than the others—that is, to remove the products of decomposition as quickly as possible. Cleanliness, the adage says, is next to godliness. Mr. Simon has modified this, and tells us that of all our present removable causes of disease uncleanliness is the most deadly; and Burdon-Sanderson tells us that the only scientific definition of filth is that it consists of the products of bacterial evolution. If the septic poison be not introduced too quickly, too frequently, or in too large a quantity, the living blood and tissues will decompose and neutralize it. They are the best colytics. All collections of blood and liquids must be prevented. Liston did this by leaving the wounds after his operations exposed to the air for five or six hours, or covered with lint dipped in water till all oozing had ceased and the surfaces were glazed over, and then brought them into apposition. This was before the days of antiseptic surgery, yet the wounds were not poisoned by atmospheric germs. Lister leaves drainage-tubes in the wound to carry off the fluids as formed. In obstetric practice we must depend on the natural drainage and on frequent washings by the syringe. Billroth says that in ordinary wounds the secretion poured out within the first forty-eight hours is especially active, and that the stinking products of tissue decomposition are possibly the least noxious. This does not seem to me to hold good of the discharges after delivery, but let it be so or not we must ever bear in mind that uncleanliness must be reckoned as the deadliest of our present removable causes of disease.

The next group we have to consider is so closely connected with the former that it will not be necessary to dwell on it at any length. Since the days of Hippocrates it has been known that portions of the placenta, or membranes, or clots, retained within the uterus will cause fever. As in the laboratory, infusions made of fragments of organic matter, animal or vegetable, afford the material on which bacteria may work and elaborate septic poison, so will organic substances retained in the uterus afford the conditions for the formation of septic poison, which, when it gets into the system, will set up fever. Harvey, of whom it has been said that if he had not been a great physiologist, he would have been a great obstetrician, washed out the uterus under these circumstances; but it is to Dr. Braxton Hicks we are indebted for formally recommending the practice. The rapidity with which the fever subsides when this is sufficiently done proves that the fever depends on the absorption of the poison.

Closely connected with these groups is another set of cases where the disease takes its origin in varicose veins, which inflame, and in which thrombi form, giving rise to emboli and pyæmia with metastatic abscesses. Bacteria make their way into these thrombi, from within the system, and cause them to disintegrate and break into fragments, which, being carried off in the current of the blood, get arrested at certain points and give rise to secondary inflammations and metastatic abscesses.

The foregoing groups belong to the class Dr. Barnes calls autogenetic. Autogenetic they are so far as the primary factor for their production is concerned, but for their development they require the presence of organisms to carry on the manufacture of the posion—that is, the active agent in their production. The cases we have next to consider present a different clinical history, and seem to depend on entirely different causes. Those we have been considering occur only after labor, and have their origin in conditions caused by labor. They occur in isolated cases, are not infectious, and do not spread through whole communities. In the cases we have now to consider the disease may manifest itself before labor has set in. It seizes great numbers at the same time; it observes cycles of development and decline, sometimes disappearing altogether for long or short periods; at its onset it proves fatal to almost all who are attacked by it, as it declines it becomes more mild in its character, and many of those attacked recover. In all these respects these cases resemble diseases specific in their nature, and dependent for their development on the action of a specific epidemic influence.

The occurrence of fever before labor, which rapidly develops after delivery into puerperal fever of a very fatal character, has been noted and described by many observers. In the following cases all the facts seem to be so fully verified as to leave no room for doubt: A lady, mother of several children, residing in a healthy situation, in a large and well-kept house, when expecting her confinement, had one of her children under the care of Mr. Wheeler for club-foot. Not feeling very well she spoke to Mr. Wheeler about herself, and he prescribed a diaphoretic mixture. Next day Mr. Wheeler finding the fever increasing, and knowing that she was in hourly expectation of her confinement, advised her to send for her accoucheur. Dr. William Smyly now saw her, on April 14, 1882. He found her skin dry and hot; her pulse, 120; her temperature, 104° F. The fever continued to increase till the morning of the 15th, when perspiration occurred, and labor set in. The child was born at 1.30 P.M. on the 15th—a healthy child, still living. The fever continued; though the temperature never again reached 103°, the pulse was abnormally and increasingly fast. The lochial discharge became fetid and the abdomen tympanitic. During the night of the 18th violent diarrhœa set in, with great pain. I saw her the following morning; she had then a very rapid and small pulse, the abdomen was tympanitic, the breasts flaccid, the skin relaxed, and she was gulping up mouthfuls of coffee-ground fluid, and was apparently dying, but rallied a little, and lived till the next day—the sixth after her confinement. There was no history of exposure to any zymotic disease. Her infant was born alive and healthy, and continued healthy. There was no disease in the house or family. The child under treatment for club-foot was wearing a boot, and running about in perfect health. The fever manifested itself before either accoucheur or nurse was in attendance or labor had set in, and ran its fatal course with all the characters of puerperal fever.

Epidemics of puerperal fever have been so frequently snd so fully described that it is almost unnecessary to more than refer to them. But there is one epidemic on record whose whole history can be so clearly traced that it is exceptionally worthy of attention. It occurred in Rotunda Lying-in Hospital in 1854 and 1855, and has been described by the late Dr. McClintock[1] with all the faithfulness, accuracy, and vividness of detail characteristic of him. Unfortunately time will not admit of my giving more than a brief outline of the history. It was the second epidemic Dr. McClintock had witnessed in the hospital—the first being in 1845, when he was assistant under Dr. Charles Johnson, and this one in 1854–55 when he was himself Master.

The epidemic unequivocally declared itself in the first week of December, 1854, but not unexpectedly, Dr. McClintock says, for there had been twelve or fourteen cases of puerperal peritonitis and phlebitis, together with a few isolated cases of scarlatina and typhus, in the house during the preceding nine months.

[1] Proceedings of Dublin Obstetrical Society, Dublin Quarterly Journal of Medical Science, vol. xix., p. 456.

From the beginning of December to the 14th of February, 182 women were confined—not half the average, as admissions, except in extreme cases, were stopped in the end of December, and all January.

Of the 182, 38 or 1 in 5 were unequivocally affected, and of the 38, 17 recovered and 21 died—making the proportion of fatalities 1 in 8 of all admitted, more than tenfold the average of the hospital. In three of these cases the puerperal disease was complicated with scarlatina; of these two died. One woman, who was slowly recovering from scarlatina, which came on soon after delivery, was seized with symptoms of peritonitis on the tenth day, under which she rapidly sank.

"It rarely happens," Dr. McClintock says, "that puerperal fever breaks out in the hospital without its contemporary appearance in private practice; and it never happens, I believe, that it prevails to any extent outside the hospital without appearing among the patients within its walls. On the late occasion I had reason to know that several deaths had occurred from the disease among women confined at their own homes, and lacking neither comfort nor attention, before it visited the hospital. Nor since then were its ravages confined to the poor inmates of our wards, for many women among even the upper classes of society were carried off under its fatal influence. During the months of December and January no less then twelve of such deaths, in and about Dublin, came to my own knowledge, and I have heard of four or five more in the beginning of last month" (February, 1855).

On the outset of the fever in the hospital it displayed uncommon virulence, and the first seven patients who were attacked fell victims to its malignity.

The progress of the epidemic is shown by the number attacked on different successive days. Thus, on each of the following days—viz., the 1st, 3d, 4th, 6th, 9th, 10th, 11th, and 12th December, there was one woman seized with the disorder, three on the 13th, and three on the 15th, and on no subsequent days of this month was there more than one, and on many days not one was attacked; but in February two were attacked on the 8th, two on the 9th, and two on the 10th.

With respect to the period after delivery at which the patient was seized the following are the general results:—2 were attacked in three hours from the completion of labor, 1 in four hours, 1 in twelve, 1 in fourteen, 1 in seventeen, and 1 in twenty-two hours. Each of these seven cases terminated fatally. One was seized in twenty-two hours after delivery, and 1 in twenty-three—the former recovered, and the latter died. Thus we see, of 9 patients in whom the complaint manifested itself on the first day of childbed 8 died; 12 were affected on the second day, 6 of whom died; 10 were attacked on the third day, and of this number the complaint proved fatal to three.

Here, then, is a disease which approaches gradually, which suddenly acquires such force as to make the mortality of a hospital nearly tenfold, which at its onset caused the death of all who were attacked by it, which affected the city at large, which manifested itself sometimes within three hours of the patient's delivery, and which gradually exhausted its violence and ceased. Is not this the history of an epidemic? Does it not remind one of the history of cholera, or of small-pox, epidemics of which are also characterized by their gradual approach, marked by sporadic cases, their furious onslaught and their gradual subsidence indicated by diminished violence and the increased number of recoveries?

Epidemic diseases vary as to the mode of their commencement. Generally their advent is heralded by the occurrence of isolated cases at varying intervals. It was thus in the epidemic of 1854–5, of which we have been speaking, and in that of 1826, described by Dr. Collins. In the epidemic of 1845, also described by Dr. M'Clintock, there were no indications of its approach. Its invasion was sudden and unexpected. It sometimes disappears abruptly, as in that described by Dr. Collins: "In the year preceding my appointment as Master," he says, "which took place in November, 1826, puerperal fever prevailed in the hospital to an alarming extent. In the succeeding year, 1827, the mortality from this disease was slight. Typhus fever was, during these periods, very prevalent in Dublin, and many cases of it appeared in hospital. In 1828 the attack of puerperal fever was much more severe, proving fatal to twenty-one women. It continued to increase in violence considerably in the months of January, February, and March, after which it disappeared, and for the four remaining years of my Mastership we did not lose a single patient from this disease."

During these four years 10,785 patients were delivered in the hospital, of whom only 58 died, which is nearly in the proportion of 1 in 186, or 0.54 per cent.—the lowest mortality on record—in an equal number of a similar class of patients, as Dr. Collins, writing in 1836, remarks, and now, in 1884, the same remark, I believe, holds good. The mortality of lying-in hospitals may be taken as depending on the extent to which puerperal fever prevails. For short periods, when fever is absent, the average is low, but when the observation extends over a longer term the average is equalized.

The whole mortality of the Rotunda Hospital, from its opening in 1757 to the close of Dr. Shekleton's Mastership in 1854, nearly one hundred years, was at the rate of 1.21 per cent. As we have just seen, during the four years after the epidemic of 1826 it fell to 0.54, but during the whole seven years of Dr. Collins' Mastership it was 0.96. During the seven years of Dr. Evory's Mastership, 1794–1800, it was lower, 0.75. From 1781 to 1786 under Dr. Rock, it was 0.76, and in the report just published for the year 1883 it was 0.55.

Epidemics of other diseases, small-pox for example, subside as completely as did that of puerperal fever in 1826, but they more frequently linger on, the epidemic influence getting less and less active till a new wave approaches, and overlaps that which was disappearing. This seems to have been the case in the epidemics of 1845 and 1854. The report of the hospital published by Johnston and Sinclair of the seven years preceding Dr. M'Clintock's Mastership, enables us to trace it. Unfortunately we have no details for 1846, but in 1847, when Dr. Charles Johnson's Mastership terminated and Dr. Shekleton's began, the disease was still prevalent, or probably there had been a recrudescence of the epidemic. During the months of November and December of that year, with which the report commences, the total mortality was at the rate of 7.02 per cent. In the following year it fell to 1.81 and continued to fall till 1852, when it reached the minimum of 0.56. The new wave now manifested itself. In 1853 the mortality was 0.88; in the beginning of 1854 it was 1.13; and in the latter months of that year the epidemic, as we have already seen, was in full force, and the mortality reached 11.53 per cent.

The following tables, calculated from Johnston and Sinclair's report, show the total mortality and the mortality from puerperal fever:

TABLE I.—*Total Mortality.*

1847 Nov. & Dec.	17	in	242	deliveries	= 7.02	per cent., or 1 in 14.23
1848	33	"	1,823	"	= 1.81	" 1 " 55.2
1849	37	"	2,063	"	= 1.79	" 1 " 55.7
1850	17	"	1,982	"	= 0.85	" 1 " 114.0
1851	14	"	2,070	"	= 0.67	" 1 " 147.8
1852	11	"	1,963	"	= 0.56	" 1 " 178.0
1853	17	"	1,926	"	= 0.88	" 1 " 113.3
1854	19	"	1,679	"	= 1.13	" 1 " 88.3
Total ...	165[1]					

[1] An error of 2, owing to a misprint in the Report. Total mortality from all causes was only 163 = 1.85 per cent.

TABLE II.—*Puerperal Fever.*

1847 Nov. & Dec.	} 10	cases of	puerperal fever,	9	died, = 90	per cent.
1848.....	43	"	"	23	" = 53.48	"
1849.....	29	"	"	19	" = 65.55	"
1850.....	15	"	"	2	" = 13.33	"
1851.....	10	"	"	5	" = 50	"
1852.....	3	"	"	2	" = 66	"
1853.....	8	"	"	5	" = 62.5	"
1854.....	11	"	"	10	" = 90.9	"

In Dr. M'Clintock's report of the epidemic of 1854–5 it appears the hospital was closed in the latter part of December and all January. It is not directly so stated, but it would appear that it was opened again in February, but the disease showed itself among the new set of patients—two were attacked on February 8th, two on the 9th, and two on the 10th. We had a similar experience in the Coombe Hospital in the early part of 1880. The hospital was completely rebuilt and newly furnished three years before. Fever manifested itself in the early part of the year, and in March the hospital was closed. The whole house was cleaned, the walls and ceiling scraped and whitened, the floors saturated with wax and turpentine, and everything thoroughly cleaned. It was re-opened in April, every alternate bed being left unoccupied; again the fever showed itself, and again the house was closed. The hospital consists of two buildings, about twenty yards apart from one another. The second building is used for gynæcic cases. The patients were transposed—the gynæcic cases were moved to the labor wards, and all new labor cases were taken into the gynæcic wards; but again the fever manifested itself among the labor cases. The other patients (transferred to what was supposed to be an infected house) remained perfectly healthy. The evidence here seems conclusive that the disease was not the result of "Hospitalism."

Another feature of the disease of almost equal importance manifested itself on this occasion, as showing its true nature. As the epidemic subsided, and the patients who were attacked began to recover, they got pelvic cellulitis, and at the same time many cases of the same kind came into the house from among the patients who had been confined at their homes. At first, suppuration and the formation of abscesses was the rule in these cases, but after a little the majority got well by resolution. The epidemic had expended its force.

In many of the recorded epidemics the occurrence of cases of typhus fever and of scarlatina at their beginning is noted, and it might be said that they were epidemics of these diseases and not puerperal fever at all.

The eighty-nine cases recorded by Dr. Braxton Hicks in his paper on "Puerperal Diseases"[1] may lead some to adopt this view, but a careful examination of his cases will show that they prove only that scarlatina and other diseases may, and frequently do, occur in the puerperal state. They occur in a similar manner after surgical operations, and seriously influence the result, but do not prove that puerperal is scarlatina fever, or the converse. If you sow thistles you will grow thistles, and if you sow scarlatina the crop will be scarlatina. One case mentioned by Dr. McClintock affords evidence, however, of the clearest character that the disease was not scarlatina. "A woman recovering from scarlatina, which attacked her soon after delivery, was seized with symptoms of peritonitis (phrase often used by Dr. McClintock as synonymous with puerperal fever) on the tenth day, under which she rapidly sank." It must be admitted that it is in the highest degree improbable that if the epidemic disease was scarlatina it would affect a patient in this manner who was only just recovering from the same disease. It is worthy of remark that, though he makes special allusion to the health of the children, and to the absence of trismus and convulsions, which had been of frequent occurrence in the epidemic of 1845, Dr. McClintock does not describe a singe case of scarlatina as having occurred among the children of the women attacked by puerperal fever. Nor can it be said the patients died too soon to allow of the appearance of the characteristic eruption. The eruption of scarlatina appears on the second day of the fever. None of the patients died within this time; one died in 50 hours from the period of invasion, one in 60, and two in 72. These were the most rapid cases. Four or five days was the average time that patients lived after being seized with a fatal attack of the fever.

The foregoing evidence seems to me to prove irresistibly the existence of a specific epidemic influence. Much more might be adduced to the same effect. Dr. Lusk[2] tells us that in the year 1871 the mortality from childbed in New York was 399; in 1872, 503; in 1873, 431; in 1874, 439; and in 1875, 420. The excess in the deaths for 1872, he says, was due wholly to an increase in the cases of metria, those from ordinary accidents remaining nearly the same as in the preceding years. The disease certainly did not extend into the city from the hospitals serving as foci, for the mortality at Bellevue Hospital was scarcely more than half the usual average. There was no especial mortality that year from either diphtheria, erysipelas, or scarlatina, but the aggregate mortality was the largest known in the history of the city.

Dr. Fordyce Barker, in the recent discussion at the New York Academy of Medicine, alluded to the great puerperal mortality of 1872, and attributed it to epidemic influence. In five of the best wards of the city, he said, in which are the residences of a great proportion of those of wealth, and few of the class of dwellings known as tenement houses, with a population of 307,046, there were eighty deaths from puerperal fever, while in the remaining wards of the city, with a population of 605,245, there were but sixty-three deaths—that is, nearly one-third less, in proportion to the population, than in the best parts.

Epidemic disease is defined to be "a disease prevalent among a people or a community at a special time, and produced by some special cause or causes not naturally or generally present in the affected locality, as distinguished from an endemic disease."[3] The facts now mentioned seem to me to prove that there is a large group of puerperal cases that come strictly within this definition, and that the epidemic thus constituted is a specific disease.

It is taught, however, by many that puerperal fever is nothing else but poisoning with septic matter from the genital organs.[3]

This theory seems to me to be defective, inasmuch as it does not embrace the foregoing facts.

As stated by Schroeder, it involves the following propositions:

1. Puerperal fever is caused by the absorption of septic matter from the genital organs. It is nothing but poisoning with septic matter.

2. The infecting matter is found everywhere where organic compounds decompose. It may be derived from dead bodies, suppurating wounds, disintegrating neoplasms, and especially the secretions of diseased and sometimes also of healthy puerperal women.

3. Fresh wounds are necessary for the absorption of septic matter. Wounds in a state of granulation do not absorb, but if the granulations be absorbed, or the surface of the wound broken, then it becomes an absorbing surface.

4. The septic matter is never absorbed through the intact skin or mucous membrane, through the lungs or intestinal canal.

5. The septic matter may be generated within the patient herself—self or auto-infection; or be introduced from without—external or hetero-infection.

6. Self or auto-infection is most likely to occur when the wounds are fresh—that is, when at the birth of the child there are already decomposed materials, as from a

[3] A Manual of Midwifery. By Karl Schroeder.

decomposed fœtus, gangrene of the soft parts established before delivery, or when new growths, as carcinoma, rapidly undergo decomposition. Retained membranes and placentæ are rarely the cause, because by the time they begin to decompose the wounds have ceased to be in an absorbing condition.

7. Hetero-infection, or infection from without, arises from the direct application of septic matter to recent wounds in the genital organs by means of the sponge or linen used in cleaning the parts, by instruments, or by the examining finger. It takes place most frequently through lacerations in the cervix.

8. It may possibly be caused by septic matter floating in the air, but there are no cogent reasons for such an assumption.

9. The definition shows there is nothing specific in puerperal fever. It is the same state which is frequently observed in surgical wards, and designated as erysipelas, pyæmia, ichoræmia, and septicæmia.

Such is the septicæmic theory as to the nature of puerperal fever. Those who hold it look on the disease as preventable, and assert that its occurence is due either to ignorance of the precautions necessary to prevent it, or to failure in seeing that such precautions are rigorously carried out. These precautions are of a very elaborate character. They have been very fully set out in a paper read before the New York Academy of Medicine in December last, by Dr. Gaillard Thomas. They are to be put in force in private dwellings of all classes as well as in hospitals. When a confinement is expected the patient's room is to be carefully prepared, all curtains and upholstery to be removed, the ceilings and floors are to be washed with a solution of carbolic acid or bichloride of mercury. The bedstead and mattress to be sponged with the same solution. The nurses and physician are to take care that all their clothing is free from septic infection. If they have been exposed to the effluvia of septic diseases, such as typhus or erysipelas, their clothing is to be changed and their bodies thoroughly sponged with a saturated solution of boracic acid. As labor sets in the nurse is to wash her hands, remove the dirt from under her nails, and give the patient an antiseptic injection every four hours. The physician is also to wash his hands and attend to his nails; and, after washing, both doctor and nurse are to soak their hands for several minutes in a solution of bichloride of mercury. Labor being complete, the third stage being carefully attended to, the physician is to examine the vulva of the patient; if the perineum have been ruptured it is to be closed by suture; if slight lacerations have occurred they are to be dressed with a solution of carbolic acid and persulphate of iron, and painted over with collodion. The patient is to take ergot three times a day for a week, to have the vagina syringed out with an antiseptic lotion every eight hours —twice as often if the labor has been an instrumental or difficult one—and, after each syringing, a pessary of iodoform and cocoa-nut butter is to be introduced into the vagina, the nurse being careful to disinfect her hands before every approach to the genital tract of the woman.

In corroboration of their views, the advocates of the theory appeal to the results which they have obtained by adopting some such mode of preventive treatment as that laid down by Dr. Thomas. But the history of great hospitals, such as that of Dublin or Vienna, shows that puerperal fever will prevail and cause sad mortality at times, and disappear again, and that the conditions governing its movements have not yet been discovered. Dr. Collins' precautions, compared to those recommended by Dr. Thomas, were very simple indeed. "All the beds in the hospital are composed," he says, "of straw, nor is any one used more than a second time without the cover having been washed and the straw renewed. In every instance where the patient *dies* this is at once done, and, should the most remote symptom of *fever* have been present, every article connected with the bedding is instantly scoured and stoved; the wood-work and floor washed with the chloride of lime solution, and the entire ward whitewashed."

To these precautions, along with strict attention to ventilation, he attributes the complete disappearance of puerperal fever, and the fact that his mortality during the last four years of his Mastership was the lowest that had ever been recorded. The gentleman who immediately succeeded Dr. Collins in the Mastership was his near relative, his pupil and assistant, and it may be fairly assumed did not relax his attention to the means that had been so successful with his predecessor; yet we find that the mortality during his Mastership was nearly double the total mortality of Dr. Collins' Mastership, more than three times that of Dr. Collins' fours years' exemption from fever, and the highest recorded in the hospital during the first hundred years of its existence.

The experience of the Vienna hospital is not less remarkable. "It is familiarly known," Dr. Lusk tells us, "that after Semelweiss had introduced the practice among the physicians attending patients at the large lying-in hospital at Vienna of washing the hands in a solution of chloride of lime, there was a great diminution in the mortality which prevailed, notwithstanding which G. Brann reports, however, that in 1857, in the month of July, in 245 deliveries there were 17 deaths. The following month Prof. Klein gave orders to suspend the use of disinfectants. By chance in August there were only 6 deaths out of 250 confinements, and in September of 275 patients none died. From 1857 to 1860 the mortality was slight, though disinfectants were not used; while during the three following years, in spite of the systematic and persistent employment of those agents, the death-rate once more assumed formidable proportions."

Such experiences are no doubt discouraging. The precautions of the present day are, however, much more elaborate than those of Collins and of Semelweiss, and, let us differ as to our theories as we may, we will all unite in the earnest desire that they may prove, not only still more efficient, but more permanent in their effects.

CEREBRAL LOCALIZATION—THE CENTRES FOR VISION.

By PHILIP ZENNER, A.M., M.D.,

CINCINNATI, O.

The present theories of cerebral localization, which assign to the various parts of the cortex distinct and different functions, are of very recent origin. The teaching of Flourens, that the removal of any portion of the hemispheres will affect all the cerebral functions alike, and that therefore every part of the cortex performs the same functions, had complete sway in the medical world for nearly half a century. The observations of Broca, that certain disturbances of speech were apparently caused by lesions in a limited part of the frontal lobes, were the first to point to the incorrectness of that teaching. Then Meynert made his profound researches in the anatomy of the brain, and with an acumen rarely equalled, combining the results of anatomical investigations with clinical and pathological observations, concluded that the anterior portion of the hemispheres possessed motor, the posterior sensory functions. Hughlings-Jackson, also, through pathological and clinical studies, arrived at similar results as to the motor areas. Lastly, a long series of experiments in animals seemed to confirm previous results, and to map out with wonderful precision a new cerebral topography.

These theories of localization, arrived at by so many and independent methods, seem but a necessary corollary of a deeper insight into the nature of psychical activity. Nevertheless they have not yet found general, or, at least, not universal acceptance. Some observations in man, but especially the experiments of an eminent physiologist—Goltz, of Strassburg—have apparently afforded a well-grounded doubt of the correctness of what had al-

most been accepted as ascertained facts. Goltz arrives at conclusions very similar to those of Flourens.

In this state of uncertainty apparently existing, it may not be without definite results to examine the subject from a very limited standpoint; and, taking in consideration all the means of research, attempt to arrive at positive conclusions as to the localization of a single cerebral function.

I propose in these papers to thus investigate the subject, the cerebral centres for vision. It will be my effort to bring to bear in that investigation all that has as yet been contributed that is of value in its elucidation. While I attempt to treat the subject as briefly and clearly as possible, I wish to enter sufficiently into detail to enable each reader to draw his own conclusions from the data given.[1]

To facilitate our investigations, we will examine the subject from three various standpoints, that is, the evidence afforded by anatomical, physiological, and pathological data.

ANATOMICAL DATA.

The optic nerves and their prolongations, the optic tracts, can be followed with little difficulty into some of the large ganglionic masses at the base of the brain, that is the optic thalami, the anterior corpora quadrigemina, and the external and internal geniculate bodies. The fibres passing to the internal geniculate bodies, and therefore these bodies themselves, are not connected with the sense of vision. This knowledge is gained from experimental and pathological observations, some of which will be mentioned further on, but need not be considered now. The other ganglia mentioned—the optic thalami, or rather the nuclei of gray matter, in their posterior portions termed pulvinar, the external geniculate bodies, and the anterior corpora quadrigemina—may then properly be termed the basal ganglia of vision. From these masses of gray matter fibres pass in the corona radiata to the cortex of the hemispheres. Such fibres were already clearly observed by Gratiolet and described as optic radiations, and were, at a later period, more fully traced out by Meynert. These optic radiations were described as passing from the ganglia at base to the cortex of the occipital and temporal lobes; but the fibres passing to the latter are apparently those coming from the internal geniculate bodies, and therefore are not connected with vision. In the most recent systematic work on the anatomy of the brain (Wernicke, 1881), the optic radiations are described as passing only to the occipital lobes.

This anatomical exposition might be deemed sufficient for the solution of our problem, and give us the requisite information as to the part of the cortex in which is situated the centre for vision. For the optic nerves, whose functions are known, are distinctly followed into one set of ganglia, and from the latter other fibres are described as passing to a limited portion of the cerebral cortex. And, in fact, these anatomical data would be quite sufficient for our purposes if every part could be established beyond a doubt. But we are dealing with the most intricate parts of the bodily organism, where facts are largely inferred rather than clearly seen and proven. It cannot be stated with certainty from the simple anatomical investigations that the fibres passing to and from the basal ganglia are either the immediate or mediate continuations of one another, nor amidst that interminally intricate network of the centrum ovale, that the so-called optic radiations pass only to the occipital lobes. If both these facts be proven, we then have cause to admire the success of those indefatigable anatomists who were first to point out great physiolgical truths, but their researches alone can scarcely be accepted as proving these controverted points. But while such difficulties are encountered in tracing out, by ordinary methods, the course of nervous strands amidst countless intermingling strands of the same kind, we are often greatly assisted by the results of certain pathological changes. Thus degenerative changes may occur in a single system of nerve fibres which will enable us to distinguish it from the surrounding healthy tissues and follow its whole course from its inception to its termination. Such degenerated tracts, subservient for anatomical and physiological studies, are sometimes found after pathological lesions, or may be directly obtained by experimental destruction of tissues. Waller, an English physiologist, pointed out, many years ago, the cause and course of these secondary degenerations in developed nervous tissues. The principle proclaimed by him, and since termed the Wallerian law, is that nervous tracts degenerate when separated from their nervous centres. They degenerate in the direction in which they convey impulses, those conveying centripetal impulses in a centripetal, those conveying centrifugal impulses in a centrifugal direction, and throughout their whole extent beyond the point of injury, no matter whether they be fibres in a peripheral nerve or in the central nervous system.

To what extent this Wallerian degeneration will assist us in our present anatomical studies will appear further on. But far more valuable in these investigations are degenerative changes following destruction of different parts at the earliest periods of extra-uterine life; for here there occurs, in addition to the secondary degenerations, a lack of development in the tissues, and thus whole nervous strands can be more distinctly mapped out. This method was first methodically instituted by von Gudden, of Munich. He enucleated the eyes of new-born animals, also removed various parts of the brain, and when the animals arrived at comparative maturity, noted the changes resulting from these early mutilations. He states that, when under such circumstances a nervous tract is severed, it will degenerate throughout its whole extent. Also atrophy of nervous centres may follow such injuries. Thus in case one centre is destroyed which is a source of excitation to another, then the latter degenerates. This degeneration in the excited centre will occur if only its connection with the exciting one is severed. But an influence in the opposite direction, that is, of the excited on the exciting centre is not found. It is possible that this law of Gudden does not properly represent all the facts in the case; but, as we will see immediately, it at least enables us to differentiate and follow the course of separate anatomical tracts. It need scarcely be mentioned that we will consider results thus obtained only so far as they throw light on the centres of sight.

Course of the optic nerve.—The first experiments of Gudden were performed for the purpose of determining the course of the optic nerves in the optic chiasms. Since the time of Isaac Newton it has been taught that in man there is a semi-decussation of the optic nerves in the chiasm, and only in recent times was that statement questioned, when, on the ground of anatomical investigations, Mendelstamm, Michel, and others concluded that there was complete decussation of the optic nerves in man. I would not enter into this question here, were it not that its answer throws light upon some of the final questions with which we have to do, and that there is a prevalent opinion that it has not yet been definitely settled.

As above stated, the doubt cast upon previous belief of semi-decussation arose simply from anatomical investigations, and these are quite insufficient to decide this matter.

Meynert, than whom there has been no abler researcher into the cerebral structures, after a careful examination of prepared sections, stated that he could not therefrom determine whether there was complete crossing, or semi-decussation of the nerves in the chiasm; and Gudden, in explanation of this difficulty, states that in addition to

[1] When writing this paper I was not aware that the subject had been previously treated in a similar manner, but have since received a work of Mauthner's (Gehirn und Auge, 1881) wherein he goes over the same ground. But inasmuch as the most valuable part of the material here collected together has been contributed since Mauthner's book was published, I trust these papers will not be without value in conveying knowledge of what has already been acquired on this subject, or removing any doubts formerly entertained.

the endless entanglement of the fibres, they pass from higher to lower planes in their course, and therefore could not possibly be followed throughout an anatomical section. H. Müller[1] asserted as a law that in animals with monocular vision there is complete crossing of the optic nerves, and that as the axes of the eyes become more nearly parallel, and therefore there is more complete binocular vision, there is more nearly a semi-decussation of the nerves in the optic chiasm. In fishes there is complete crossing of the nerves. Here the crossing is very evident, as the two nerves merely overlie one another in crossing. Gudden at first believed that the same was true of rabbits, until his experiments taught him that here a small part of each optic nerve passes into the optic tract of the same side. Gudden's[2] experiments for the purpose of determining the course of the optic nerves were first performed on dogs and rabbits. He enucleated either one or both eyes very soon after birth, and when the animals had arrived at comparative maturity, killed them and carefully examined the removed parts. He found, in dogs, after enucleation of one eye, atrophy of the corresponding optic nerves, and reduction in size of both optic tracts, that one being always the smaller which was on the side opposite to the atrophied optic nerve. Similar changes could be produced by destruction of the visual ganglia. When the left external geniculate body, anterior corpus quadrigeminum, and optic thalamus had been destroyed, there was complete atrophy of the left optic tract, and reduction in the size of both optic nerves, the right being smaller than the left. If both eyes were enucleated, atrophy of both nerves and both tracts followed. These results of Gudden had been corroborated by various other experimenters, some of whom will be referred to farther on. If after them there could be any doubt of the semi-decussation[3] of the optic nerves in the higher animals, this doubt would be removed by the later experiments of Nicati,[4] in which, after the median, antero-posterior section of the chiasm in cats, the latter still retained their vision. Similar experiments have since been made by Bechterew[5] on dogs with like results. Atrophy of both optic tracts in man, after blindness in one eye and atrophy of the corresponding optic nerve, has been recorded by Gudden,[6] Adamük,[7] Putscher,[8] Marchand,[9] Deutschman,[10] Burdach,[11] and others, and we will have occasion to mention at a later period cases in which with disease of one optic tract blindness on the same side of each eye was observed during life.

Relation of optic nerves to visual ganglia and cerebral hemispheres.—We have thus been enabled to follow the course of the optic nerves through the chiasm and optic tracts, and must now attempt to follow the latter into the cerebral ganglia and hemispheres. Their primary termination is very easily determined. After enucleation of the eyes, by the method above mentioned, there is found atrophy not only of the optic nerves and tracts, but also of the anterior corpora quadrigemina, the external geniculate bodies, and the posterior gray nucleus of the optic thalamus (pulvinar). The atrophy of these ganglia occurs so uniformly that we need not hesitate in stating that they are immediately connected with the optic nerves, and therefore directly related to the sense of vision.[12] For the sake of brevity I will hereafter speak of these ganglia conjointly as the primary visual centres. Our next object must be to determine their relation to the hemispheres.

[12] In some of the instances mentioned, of atrophy of optic nerves in man being followed by atrophy of both tracts, degenerative changes in these ganglia on both sides was also observed.

With this object parts of the hemisphere were removed in new-born animals, and after sufficient time had elapsed the efforts of such mutilations were carefully observed. Such experiments were made by Gudden[1] and Ganser,[2] of Munich, and Monakow,[3] of St. Pirminsberg, Switzerland. The results of these experiments all coincided in so far that removal of the posterior part of a hemisphere was followed by a degree of atrophy of the primary centres of the same side.

The most valuable experiments were those of Monakow. He always succeeded in obtaining atrophy of the primary visual centres in rabbits after removal of a very limited portion in the occipital region, a part corresponding to the area in the dog which Munk has termed the visual area, of which we will soon have occasion to know more. Monakow also found that removal of other parts of the hemispheres, while followed by atrophy of other subcortical centres, did not affect the primary visual centres, so that the conclusion appeared logical that the latter are anatomically connected with a limited area of the cortex in the occipital region.

Nevertheless such conclusions might be too hastily drawn. For in these experiments not only is the cortex removed, but the underlying white brain matter necessarily injured, and thereby fibres may be severed which pass to other portions of the brain. To avoid this source of error Monakow resorted to another series of very careful and ingenious experiments (on rabbits). After removal of the area in the occipital region already referred to, he found not only atrophy of the primary visual centres, but also atrophy of the fibres of the corona radiata passing from this part of cortex to these centres. He now severed these fibres in the midst of their course, and subsequently observed the effects of their division. (Operation, like the others, on new-born animals, which were then kept alive for weeks or months.) In such instances there was subsequently found atrophy of the severed fibres of the corona radiata both on the peripheral and central side of the section—the same changes in the primary visual centres as after removal of the hemispheres—and atrophy of the corresponding part of the cortex. A microscopical examination of the latter showed that only a part of the cortex was atrophied—the third and fifth layers—those containing the large pyramidal cells.

This experiment was made many times, so as to secure accuracy both as to the locality and nature of the changes, and seems to leave no room for doubt that, in rabbits, the primary visual centres are directly connected with a limited area in the cerebral cortex.

The primary visual centres are, then, connected on the one side with the cortex through fibres of the corona radiata, on the other, with the retina through the optic nerves. Each set of fibres probably terminates in these ganglia, and, it will not be difficult to show, are mediately or immediately connected with one another. The atrophied elements found in these ganglia after removal of the eye or cortex are different according as the one or other is the source of atrophy. Some layers uniformly degenerate when the eye is removed, others when part of the brain has been extirpated. Nevertheless there are certain parts which atrophy alike from either cause, proving the relationship of the two systems of fibres.[4] But this relationship can be more positively proven in another way, that is, by the atrophy found in the optic nerves subsequent to removal of those portions of the cortex with which we are now concerned. It is true, in rabbits, after removal of the hemispheres degenerative changes cannot be followed beyond the primary visual centres. But in rabbits the hemispheres are so little developed that their destruction does not appear to have a far-

[1] Loc. cit.
[2] Archiv f. Psychiatrie, Bd., xiii., 1882.
[3] Ibid., Bd. xiv. 1883.
[4] It would lead too far to enter further into the subject here. For the microscopical structure of these ganglia, and the changes taking place in them in these experiments, I must refer to the original works of Ganser and Monakow.

reaching influence on the peripheral nerve structures. But it is quite different in higher animals, where the hemispheres are more fully developed. In a dog (Gudden)[1] and in cats (Ganser and Monakow) removal of a hemisphere was followed not only by the usual changes in the primary visual centres, but also by atrophy of the corresponding optic tract, and in both optic nerves, proving indubitably the direct relationship between the hemispheres and optic nerves. The exact portion of the hemispheres was not determined, though in all of them the posterior part was removed. But Monakow believes—inasmuch as he succeeded with small mutilations in the occipital region in producing these changes, while the removal of large parts of the frontal lobes caused no changes in the optic nerves—that the cortical visual area is in the same part in cats and dogs as he had already located it in rabbits.

Experiments have also been made in an opposite direction, that is, to determine the effect of enucleation of the eye on the cerebral cortex. Munk [2] and Vulpian [3] have observed atrophy in the occipital region as the result of such experiments (on dogs), but inasmuch as others, Furstner [4] and Gudden [5] (on dogs), and Ganser [6] and Monakow [7] (on cats), have obtained negative results, we must leave this question as still open. But it is not probable that much can be gained by such experiments, both on account of the improbability of decided changes occurring, and the difficulty of detecting them if any exist.

It is quite justifiable to draw from the above experiments certain, though guarded, conclusions as to the anatomical relations in man. But Monakow, to whom we owe so much of the above researches, has also been enabled to make some observations on human beings which add to the force of such conclusions. He had an opportunity to examine the brain of an eight-months' fœtus with a parencephalic defect in both hemispheres. There was entire destruction of both occipital lobes, and of the superior portion of the parietal lobes, and, as a result (for everything pointed to its being secondary to the former), atrophy of the primary visual centres and both optic nerves and tracts. In another case, a man seventy years of age, there was softening of the occipital lobe of probably five years' standing, and also atrophy of the corresponding primary visual centres, and optic tract, and nerves. In both these instances, it is true, the disease involved also the white substance of the brain, so that taken alone they do not prove that the affected portion of the cortex is connected with the optic nerves. But taken together with the facts, that, in these instances, other subcortical centres, not in relation with the occipital lobes remained normal, these cases add greatly to the probability gained from the previous experiments that the visual area in man is in the posterior portion of the brain.

The only other observations with which I am acquainted which point directly to such anatomical relations in man are two cases reported by Hugenin.[8] In these he found, subsequent to atrophy of the optic nerves, atrophy of the "cortex of the occipital lobes, where the occipital fissure cuts into the margin of the convexity." In the first case, a man fifty-six years of age, blind three or four years in the left eye, he found these changes in both occipital lobes, but more marked on the side opposite to the affected eye. In the second, a woman forty-two years of age, nearly blind in both eyes from infancy (result of variola), he found the same changes, but alike on each side. When reported a microscopical examination had not been made.

[1] At the time Gudden attributed the changes in the nerves to accidental causes, but the results of subsequent experiments leave little room for doubt that there was here a causal relationship.

These observations of Hugenin stand alone.[1] For this as well as for other reasons, partly already referred to, they cannot be accepted as more than doubtful evidence in our present investigation. Herewith we have completed the first part of our subject, the evidence furnished by anatomical data of the locality of the cerebral centres of vision. A brief summary of what has been said will give us a clearer oversight of the subject.

1. Simple anatomical researches teach us that the optic nerves enter the primary visual centres, and that fibres pass from these ganglia to the occipital lobes. On account of the intrinsic difficulties of these investigations they cannot be accepted as conclusive.

2. Experimental investigation has proven that in higher animals the optic nerves do not entirely cross in the optic chiasm. In man the same has been proven by other means.

3. In rabbits experimental researches (Monakow) have shown a close relationship between the retinæ and a limited area in the occipital region, the visual area of Munk.

4. In higher animals (dogs and cats) similar experiments have demonstrated a relationship between the retinæ and the posterior part of the hemispheres. The exact area has not yet been definitely located, though it is probably the so-called visual area.

5. Observations on a human fœtus and pathological changes in an adult brain (Monakow), together with the former considerations, make it highly probable that the same anatomical relations exist in man.

6. Further evidence for this relationship in man are two instances (Hugenin) of atrophy of occipital lobes following atrophy of the optic nerves. But this evidence must be accepted as of doubtful value.

PRACTICAL OBSERVATIONS ON THE HUMAN EAR AND ITS DISEASES, WITH ILLUSTRATIVE CASES.

By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I.—The External Ear.

(Continued from No. 717, p. 122.)

It has been claimed that a distinction should be made between othæmatoma and "idiopathic" perichondritis of the ear. They are thus considered as separate and distinct affections by Dr. H. Knapp,[2] who says that "the majority of authors mention the inflammation of the perichondrium under the head of the much-discussed othæmatoma, with which, by Kramer and others, perichondritis auriculæ is used as a synonymous term." Dr. Knapp presents a case of the latter disease from which it is alleged no blood at any time escaped after the cyst was punctured, and that it was not, therefore, a case of othæmatoma. This statement, coming from so reputable an authority, is certainly misleading, since it is well known that in no case of othæmatoma is perichondritis absent, and that, moreover, the contents of the tumor in "othæmatoma" are frequently serous.

A peculiar variety of othæmatoma remains to be mentioned which is not always easily distinguishable from hyperæmia, a condition that I have myself only met with in the insane, where it is probably due to protracted and violent rubbing of the auricle. Any portion of the perichondrium may be involved, but it is usually limited to a small space. Thickening is often scarcely observable, and to the feel it is not "doughy." The deep-seated nature of the inflamed or congested region, however, may be discovered by stretching out the auricle between the observer's eye and a strong light. The effusion is not

[1] Mickel reported a case with extensive changes in the cortex after blindness of probably twenty years' duration. In this instance not only are the changes very diffuse, but there is no evidence that they were secondary to the ocular disease.
[2] Perichrondritis Auriculæ, Archiv. Otology, vol. ix., p. 195 et. seq., 1880.

sufficient to form a tumor; such cases seem to present the characteristics of the first stage of othæmatoma. The following case is an example of this condition.

Case V.—Ignatius J——, aged forty, was admitted to the New York City Asylum for the Insane, August 18, 1883, with dementia. Had to be fed with stomach-tube; was a mere skeleton. He finally improved very much mentally and physically, and on October 21st was up and around and eating and sleeping well. October 28th, slight hæmatoma was observed to be developing in left ear at inferior portion of concha, at its junction with the meatus. My own examination, on November 27, 1883, is thus recorded by Dr. Barclay: The left auricle, which is very thin, is of a dusky red color. The concha, which was naturally large, is much thickened as far as the meatus, and especially is it narrowed laterally by the thickening of its posterior and inner wall; it is, in fact, almost obliterated. No sacculated fluid was ever discovered.

It is notable in this case that the hæmatoma came on at the stage of mitigation of chronic meningitis, and that it was confined to the concha. Its benign condition rendered treatment unnecessary.

Termination.—It will be found that among any considerable collection of lunatics or prize-fighters, a very considerable number have their ears more or less deformed by previous attacks of othæmatoma. The writer has found this condition of things in several large asylums for the insane; and recently, in the vicinity of Madison Square Garden, on the eve of a sparring exhibition, he observed a number of persons with ears thus deformed. In some lunatics, where well-marked deformity presents itself in one auricle, the other will be found so slightly deranged as to be liable to escape detection altogether unless closely scrutinized, and in others scarcely any observable thickening will be found in the affected organ, the deeper coloring alone affording evidence to the eye, whilst the slight induration, thickening, and immobility of the skin are not to be detected without careful handling.

It seems exceedingly probable to the writer that in certain cases where the alienist is in doubt as to the sanity of a patient, valuable confirmatory evidence of previous mental trouble might be obtained by an examination of the ears. Where the deformity is great, in consequence of an extensive area of cartilage having been exposed by detachment of its perichondrium, the skin on the outer surface will usually be found to be immovable, whilst that on the inner surface remains unchanged. In these cases the concha is liable to be much reduced in dimensions, its posterior wall being often so much thickened that a narrow vertical slit only remains in front of the meatus externus, preventing the introduction of any but a speculum of the smallest size. It is scarcely necessary to add that the deformity arising from othæmatoma is not influenced by the mental condition of the patient.

The characteristic deformity resulting from othæmatoma is well shown in the following cases:

Case VI.—Joseph B——, admitted to the New York City Asylum for the Insane, May, 1883, was wild, maniacal, noisy, and violent; made unprovoked attacks on his fellow-patients; was put on sedatives and became quieter, but began tearing his clothes. About June 30th two hæmatomas of considerable size developed. He was then excitable, destructive, and filthy. The left hæmatoma ruptured about July 9th. July 30th, symptoms of excitement, etc., unabated; a slight discharge of blood from the ruptured cyst. August 30th, the left ear began to shrivel up with reabsorption of the effused fluid. Since August 20th has given very little trouble, and is now (February 4, 1884) quiet and well-behaved. Both hæmatomas are quiet, and the ears have a shrivelled appearance. Fig. 5 shows the deformity of one of the ears (the left).

Case VII.—Hugh S——, aged forty-three, admitted to New York City Asylum for the Insane, September, 1879, Was demented for one year before admission; is noisy and excitable at times. Bodily condition not good. Was discharged in September, 1880, and readmitted March 1, 1881. Is incoherent; prays a great deal—thinks he

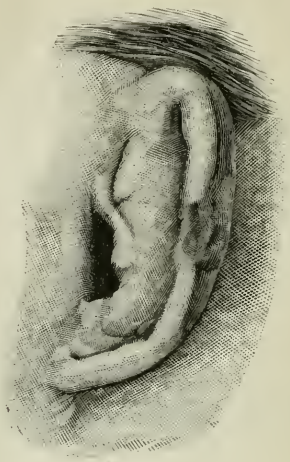

Fig. 5.

is a great sinner. March 10th, greatly excited, laughs, talks and sings; is filthy. Excitement increased during the summer, and in autumn his physical condition improved. He continued to have hallucinations, was hard to control, and tore his clothing, etc., up to the time

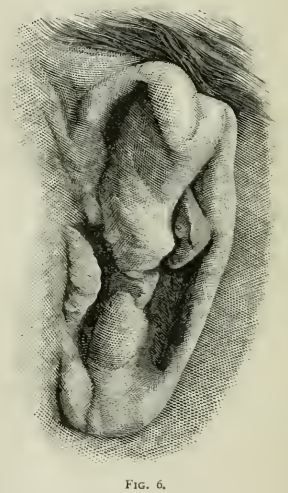

Fig. 6.

the writer saw him, in January, 1884. Fig. 6 shows the condition of the left ear.[1] The history gives no account of the time of its appearance or progress.

PATHOLOGY OF OTHÆMATOMA.

After what has been previously stated in respect to this affection there remains but little to be said concerning its pathology. Those interested in the early attempts to clear up the subject will find the matter discussed by M. Ferris, Franz Fischer, M. Foville, Virchow, and others. There seems to be but little doubt of the existence in many lunatics and inebriates of incipient

[1] The author is indebted to Dr. Trautman for the excellent photographs from which Figs. 3, 4, 5, and 6 were taken.

softening and disintegration in the tissues of the auricle, which predispose to separation of the perichondrium from the cartilage; that this is always a factor of very great importance in the production of othæmatoma may well be doubted, since the disease is scarcely ever known to occur in advanced life, when such changes would be greatest, unless mechanical agencies intervene. The extent to which softening of the cartilage may proceed without any symptoms manifesting themselves is not, of course, known, but from the following extract it is probably very considerable. Referring to the pathological histology of the cartilaginous framework of the ear,[1] Pollak shows that specimens "which were taken from the ears of individuals who had not, so far as he could learn, been affected with any form of mental disease," had "in the cartilaginous portion of the external meatus, and especially in the antihelix, small nodules" varying in size "from a mustard-seed to a lentil." These when cut open showed to the naked eye even a departure from the normal condition of the reticulated cartilage, and sections under the microscope were found to be deprived of the fibrillated network in places, and instead there was a structureless mass. In some places the breaking-down process was even more marked. Where an actual cavity was made out, it "lay wholly within the mass of cartilage, and at no point was bounded by the perichondrium, which everywhere appeared to be perfectly healthy."

From a recent examination of a very considerable number of cases of othæmatoma occurring in both mentally sane and insane subjects, and consisting of cases in progress as well as where recovery had taken place, the writer entertains no doubt in his own mind as to the universal and immediate precedence of trauma in every instance. That the pre-existence of the disintegration spoken of above in the cartilage may influence the subsequent course of the trouble must be admitted. Othæmatoma occurring in pugilists differs in no respect from that found in lunatics, its progress being influenced by the general condition and habits of the patient in both instances.

These tumors are formed of serum, or serum and blood, which is effused, not under the skin, but under the perichondrium detached from the cartilage; the contents are not ordinarily completely liquid, but are liable to contain fibrous or gelatiniform clots, which if not evacuated attach themselves to the internal surface of the sac during the process of union between the two surfaces. Union is believed to finally take place by means of an exudation of plastic lymph. It was formerly believed that the exudation produced a new formation of cartilage, sometimes constituting a uniform layer, sometimes small patches only, which was the cause of the thickening of the ears. Virchow,[2] however, alleges that the cartilage so commonly found in these cases consists of detached portions of greater or less size, which remain adherent to the perichondrium, and are not of new formation.

In its regressive course the contents of the tumor are gradually reabsorbed or a puncture gives them exit, the surfaces gradually come in contact, and the outlines of the cartilage begin to reappear, but more or less altered in distinctness. If obliteration of the cavity is accomplished by a moderate exudation of lymph uniting its walls the deformity will be slight, especially if the tumor has been but moderately distended by fluid. On the other hand, where the perichondrium has been greatly stretched by extreme distention of the sac, it contracts upon itself as reabsorption takes place, and adaptation to the cartilage as before cannot occur; the misshapen appearance of the cartilage increases with the continued contraction during the process of adhesion. The ear finally becomes indurated, and the skin on its outer surface is immovable and follows the outlines of the distorted cartilage underneath. Sometimes the organized lymph which obliterates the cavity enormously increases the thickness of the auricle, an example of which condition is shown in Fig. 6. Where a thin plastic layer only intervenes finally, as occurred in Fig. 7, the auricle is likely to be reduced in size, and becomes comparatively thin and shrivelled; in either case permanent and characteristic deformity results.

In some cases, where the effusion has been slight or imperceptible even, the plastic exudation does not form a layer of any great magnitude; the parts early are found to have a doughy feel, and but little thickening is left behind; the mobility of the skin is less affected, and consequently the ensuing deformity is scarcely recognizable.

PROGNOSIS OF OTHÆMATOMA.

This affection probably has no prognostic value in respect to the occurrence, course, or duration of insanity; but its continuance may be much influenced by the congestion or bruising to which the auricle is subject in violent lunatics and in pugilists. The trouble cannot be said to augur against recovery, since it occurs in dementia when bodily health is improving, as in Case V., nor is it obnoxious to any particular form of insanity. In Hun's reported cases, nine of the patients died insane in the asylum, nine were discharged unimproved, and six remained when the report was made—one of them in a state of dementia.

Generally the disease runs the course already described, without any complication that endangers life, although, when extravasated blood becomes putrescent there may be danger of septic poisoning. In one instance occurring in the writer's practice (Case XI.) the sympathetic irritation about the head at one time caused considerable anxiety.

Hearing undoubtedly suffers considerable impairment in some cases through the deformity of the outstanding cartilaginous framework of the ear. In the case of a pugilist examined by the writer, whose auricle was greatly disfigured, there were permanent defects in this regard, apparently due to the interference with the normal tension of the membrana tympani—*vide* Case X.

Recurrence of the tumor is, of course, impossible, where complete obliteration of the secreting surfaces has occurred, although repeated contusions in an auricle previously affected may give rise to more or less inflammation of the organ. In several prize-fighters examined, where the ears had been previously the seat of othæmatoma, constant bruising of the organ seemed to occasion very little local disturbance.

TREATMENT OF OTHÆMATOMA.

In the treatment of othæmatoma in insane and intemperate persons, among whom it mostly occurs, besides the difficulties encountered in controlling the actions of the patient, mental disease and intemperate habits exert an unfavorable influence, and thus delay recovery. Insane persons are more obnoxious to the trouble when under great excitement, as in acute dementia; and their violent and restless movements interfere very much with treatment, whilst pugilists are indifferent, and generally neglect any advice given them. It is a safe rule in the beginning to be in no haste to interfere unless rupture of the sac be imminent, since in a certain number of cases a manifest tendency to spontaneous recovery exists.

In laying out any plan of treatment in this disease, it will be well to remember that whatever the supposed cause or causes may be, we have to deal with a perichondritis, in the treatment of which we should be guided rather by its character than by its causes. And furthermore, one should be on their guard in respect to the strong tendency to interfere in these cases; this is well expressed in a paper[1] on the subject by Dr. Wallis.

[1] Monatschrift für Ohrenheilkunde, July, 1879—Rev. in A. J. O., vol. i., pp. 302, 303.

[2] Pathologie des Tumeurs, vol. ii. Paris, 1867.

[1] Loc. cit.

This author treated these tumors as abscesses, and after incision they were poulticed and treated with stimulating lotions, "but almost always with unfavorable results—grangrene, and carious destruction of the cartilage, and not rarely death, was the end." This experience induced Dr. Wallis to fall back on nutritious diet, mild cathartics, and the local application of lead wash—in all other respects treating the swelling as a *noli me tangere*. This treatment, continued for weeks, was successful in a number of cases. Fischer came to the conclusion that eight weeks' treatment affects neither the termination nor the duration of the disease, an opinion coinciding closely with the one held by Marcé, whose belief was that othæmatoma is not influenced by any treatment, but usually remains for about four months. In regard to the views above cited, however, it should be said that the fatal results alluded to by Wallis are quite exceptional, similar experiences being unknown to other writers, while Fischer and Marcé seem to have carried the expectant plan too far, since no treatment is *not* good practice in all cases.

Practically considered, othæmatoma has an aggressive and a regressive period. All cases, however, do not range themselves under so arbitrary a division, since the affection frequently remains stationary for a longer or shorter time, and very often exacerbations occur from repeated contusions of the organ.

In its aggressive stage the observer seldom is offered an opportunity to take cognizance of the incipient symptoms; especially difficult to detect is the hyperæmia, since the auricles are nearly always in a congested state in violent lunatics and inebriates. Usually a tumor is already found to exist, and the first consideration will then be to limit its extension, if possible. If it is found that the serous or sero-sanguinolent exudation is not active, and that the quantity already present is not great, we may prescribe rest for the patient, and administer small and frequently repeated doses of the tincture of aconite root with a view to arrest the activity of the circulation of blood about the head. Locally the affected region, and beyond even, may be enveloped with a coating of collodion, the gentle and uniform pressure produced by its contraction acting as a compress, and thus promoting absorption. The following case, kindly placed under my observation by Dr. W. A. Bartlett, illustrates the treatment and progress of a case of this kind:

Case VIII.—T. F. W——, aged thirty-five, a professional gymnast, was first seen on May 15, 1884. He stated that three weeks previously he had received a "cross-counter" blow upon the left ear with gloved hand. This gave rise to no pain, but, two weeks later on, the ear was again contused by a powerful blow from the foot of a person in training. The latter injury even caused no pain at the time, but twenty-four hours later (and one week before the writer saw him), after exercising for two hours the auricle was observed to be unusually warm, and several physicians who happened to be present at the time observed that it was swollen. Dr. Bartlett, who saw the case May 11th, found a fluctuating tumor on the outer aspect of the pinna the size of an English walnut, the skin over it being hot and tense. About twenty minims of serum were withdrawn by aspiration, the last few drops of which were tinged with blood. Afterward hot fomentations were applied for a day.

The writer found, four days subsequently to the above, a tumor, slightly pinkish in color, seated at the fossa of the antihelix; it had spread itself almost equally in all directions, encroaching considerably on the concha. It had partially refilled again, was "doughy" to the feel, but not tender. Hearing was unaffected. Half a drachm of straw-colored fluid was removed by aspiration, and the tumor was painted over with collodion, the patient feeling the pressure. Small doses of tincture of aconite were ordered, and rest was advised. The next day the tumor was softer, aspiration was repeated, and the treatment continued, with the addition of compression by means of padding of cotton-wool and bandaging. Tumor seemed to be *in statu quo*, effusion having probably ceased and reabsorption commenced. A notable observation was now made.

It was found that the collodion contracting upon the tumor had made it quite tense and blanched in appearance, but that with each pulsation of the anterior auricular artery (which supplies the anterior surface of the auricle) the *entrance of the blood-supply was characterized by a glow of deep-red coloring, while the subsidence which succeeded to each distention was accompanied by blanching of the parts.* The pulsations of the temporal artery were visible above and in front of the tragus.

May 19th.—Tumefaction much less; the outlines of the antihelix reappearing. Treatment continued, excepting the aspiration. May 22d, the improvement has gone on as before; treatment same; massage cautiously commenced. Progress was now uninterrupted, the massage being gradually increased in force and frequency. By the 29th inst. no fluid remained, the "doughy" feeling was less, and the collodion was omitted. The collodion during the treatment was peeled off daily and a fresh coating applied. The aconite seemed to have a notably good effect. Scarcely any deformity was observable at this time, but the concha was still smaller than normal, and the outlines of the antihelix were not sharply outlined. The patient when discharged was directed to continue the massage for some time.

Reabsorption is sometimes retarded by the general condition of the patient, and it is alleged by some authors that a comparatively scanty distribution of lymphatics characterizes this region. Whenever this tendency manifests itself, it will be well to employ measures likely to hasten reabsorption. We may act on the presumption here that the inflammatory reaction frequently attending the regressive stage is wanting or inefficient, and proceed to employ massage or pressure. In the writer's own experience the latter has been generally unsatisfactory; the application of pressure-dressings being exceedingly difficult, in lunatics especially, who are usually unwilling to allow them to remain.

We can avail ourselves, however, of the massage treatment in all cases; it consists in pressing and rolling the affected portion of the pinna between the thumb and forefinger for some minutes or more at a time. This manipulation is usually unattended by pain, and, moreover, has this advantage, that it can, when necessary, be entrusted to sane patients themselves. At first it may be practised once or twice daily, and afterward more frequently, the length of each séance being extended as treatment progresses.

The behavior of these tumors under continued and even severe bruisings is instructive. Thus the writer, assisted by Dr. W. A. Bartlett, recently made a study of othæmatomata in pugilists, which showed that recovery was not impossible under apparently unfavorable conditions, although it should be added that unsightly deformity remained. The following were among the cases examined:

Case IX.—John F——, twenty-nine years of age, intemperate, has been a boxer for ten years. Nine years ago he received a blow from "cross counter" upon left ear. The auricle became swollen, red, and tender, the pain extending all about the ear and down the neck. The tumor never opened, and became indurated in about one month. While the tumor remained "soft" it was repeatedly struck in boxing without other effect than slightly increasing the local sensitiveness. After recovery, which took place without treatment, constant bruising failed to produce a recurrence of the tumor. The outer surface of the left auricle is irregularly nodular—the fossæ being obliterated and the outlines of the ear completely destroyed, with the excep-

tion of the helix, which was not affected. The auricle is about three-fourths of an inch thick, and the concha is reduced in size, due to thickening of antitragus. The posterior surface is normal. The ear never discharged, and hearing is good.

CASE X.—Thomas A——, twenty-six years of age, has been a boxer for many years. Received a blow upon left ear from "cross counter" three years ago, producing a soft, tender swelling of the ear, and much pain in the organ and side of the head and down the neck. There was also a "numb" feeling and antophonia, which remains. Hot milk and slippery-elm poultices were applied. The tumor was at first purple in color, afterward it became red. It remained "soft" for a period of five months, during which time it was frequently ruptured by blows. Afterward it became hard and deformed. The auricle is smooth, all of the markings being obliterated except the anterior portion of the helix which is normal, and is fully one inch in thickness. The pinna seems folded upon itself from above downward. The concha is impinged upon from behind, leaving a mere slit in front of the meatus externus. There is some deafness in the left ear, due doubtlessly to the blow upon the organ. The resulting deformity is similar to that shown in Fig. 6.

In resorting to methods calculated to increase absorption, however, care must be exercised lest they increase unduly the local irritation. In relation to this matter the following paragraph is suggestive: "Physiologically the membrane of serous cavities secretes a serous fluid, which is taken up again by the vessels with great facility, this faculty of reabsorption is demonstrated by the rapid disappearance of injected fluids. But if the serous membrane is inflamed, the reabsorption of an injected fluid is impossible (Rindfleisch), and the irritation of the serous membrane determines an abundant secretion. Even a slight irritation is sufficient to transform a serous bursa into a cystic cavity. Such a transformation of a subcutaneous serous bursa is known as a *hygroma*, and may be called a tumor because of its tendency to persist indefinitely."[1] If extravasation in the beginning goes on rapidly, threatening to denude the cartilage more and more, or where reabsorption comes to a standstill, an aspirating needle may be inserted into its most dependent part and the fluid evacuated; the subsequent treatment should then consist in the methods already recommended. The evacuation of fluid may be repeated as often as the sac refills. The operation can usually be performed with the ordinary hypodermic syringe.

When the tumor is large and contains a considerable clot it is best to make an incision large enough to permit the contents, including the clot, to escape, and, since the tumor is almost sure to refill again, a silk seton may be passed through the opening thus made and brought out again above, to insure drainage. The wounds having a strong tendency to reunite should be kept open by occasionally drawing the seton through the tumor whilst pressing out the contents. As soon as the secretion lessens, its removal will be best accomplished by aspiration. It was formerly recommended to bring about adhesive inflammation by keeping up irritation with the seton, but this can be much better accomplished by massage.

When the above treatment is judiciously employed we may expect to witness a gradual diminution of the tumor and complete reabsorption of the fluid in three or four weeks; and, moreover, it is believed that much less disfigurement will ensue than occurs in cases allowed to run their course without such aid. The longer an actively progressing tumor is permitted to go on toward spontaneous rupture, the greater will be the separation of the perichondrium from the cartilage, and consequently the greater the ensuing deformity.

(To be continued.)

Progress of Medical Science.

HEPATICA—A USELESS DRUG EXCEPT TO PATENT MEDICINE VENDORS.—Messrs. J. U. & C. G. Lloyd, of Cincinnati, have been investigating the subject of liverleaf. Of late years this drug has been extensively consumed in the preparation of certain proprietary medicines. From statistics collected by Messrs. Lloyd it appears that last year over 340,000 pounds were consumed, of which amount over 300,000 pounds were imported from Europe. Four years ago the entire consumption did not reach 10,000 pounds. Our native species are named anemone acutiloba, and anemone hepatica, and very closely resemble each other except in the shape of the leaves: the former has sharp lobes to the leaves; the latter blunt lobes. Our Pharmacopœia has recognized but one species—the round-lobed form. It is proven, however, by Messrs. Lloyd, that nine-tenths of the native drug of commerce is collected from the sharp-lobed species, which has never been officially recognized. The medical properties of hepatica are unimportant. The plant does not contain an active principle, and is as devoid of characteristics as is the grass of the field. Of the vast amount of the drug consumed, it is creditable that the medical profession uses but a small per cent. Almost the entire lot is employed in the preparation of certain secret remedies.—*Drugs and Medicines of North America* (Cincinnati), July, 1884.

BICARBONATE OF SODA IN THE TREATMENT OF TONSILLITIS.—In the early stages of tonsillitis, before the pain of swallowing is excessive, Dr. Giné Partagas claims that bicarbonate of soda will arrest the inflammation. He makes the application in the following manner: The index finger being moistened is charged with as thick a layer of the powder as will adhere to it, and is then introduced into the mouth and rubbed thoroughly over the inflamed tonsil. Five or six applications are thus made at intervals of five minutes, at the end of which, Dr. Partagas claims, the patient will find the act of swallowing nearly painless. When thus employed in the early stages, bicarbonate of soda will abort the disease, and later will promote resolution. In hypertrophy of the tonsils two or three applications of the powder each day will reduce the size of the gland very considerably in one or two months.—*Journal de Médecine et de Chirurgie Pratiques*, June, 1884.

COCAIN.—Dr. Aschenbrandt, of Würzburg, has made some experiments on the action of muriate of cocain on the human organism. He administered the drug, unknown to the subjects (who were soldiers), in doses of about one-sixth of a grain in cases of exhaustion and fatigue from various causes, and found invariably that the lassitude was speedily removed, and that the men could go on for hours without feeling either hunger or thirst. One of his experiments was made on himself after a sleepless night, with the prospect of a long day's march before him, when a dose of cocain (taken in coffee about 3 A.M.) enabled him to go the whole day without feeling hunger, thirst, or fatigue, and he dined late in the afternoon with his usual appetite. He considers the drug to be a direct nerve food, and not a stimulant merely; but its stimulating action is certainly far above that of alcohol, and it appears to have no injurious after-effects.

PAGET'S DISEASE OF THE NIPPLE.—Drs. Duhring and Wile regard Paget's disease as an abnormal proliferation and degeneration of the rete, with secondary destruction of the papillæ of the corium, and subsequent development of scirrhus cancer of the atrophying variety. The cancerous change originates in the epithelium of the smaller ducts, and advances from below upward and outward as far as the skin is concerned; later it attacks the gland structure; and the retraction of the nipple is an early sign of carcinomatous change.—*The American Journal of the Medical Sciences*, July, 1884.

BABY-FARMING AS A FINE ART.

THE unique feature of a successful baby-farm, in contradistinction with all other institutions, is that the most conclusive test of merit is the small number of the graduates. This idea was aptly illustrated by a witty paragrapher on a Philadelphia paper, who imagined a lady with a burden in the form of a child going to a professional baby-farmer and negotiating for the child's board in the "home." In concluding the arrangements the lady said, "But what assurance can you give for the faithful discharge of your trust?" Proudly conscious of her peculiar abilities, the baby-farmer made reply, "Twenty-one deaths out of a possible twenty-three in the past six months." Needless to say, the new patron retired convinced she had made no mistake.

The subject no doubt is a sorry one to make a jest of, yet when the humorist strikes so true a key he may easily be pardoned for its unseemliness. Every one who has read of the exposures of baby-farming near this city must have noticed that the publication of the facts as to diet, attendance, surroundings, and large death-rate does not seem to lessen the number of children in the identical "boarding-houses" exposed. Under such circumstances it must naturally be presumed that the persons placing children out in this way do not desire the best, but do desire the worst, accommodations to be obtained. The patronage of these farms comes not from that portion of the community sometimes called the "lower" and "poorer" classes. In reality, the great majority of these unhappy infants are the offspring of well-to-do fathers or mothers, who, even with the heart-knowledge of their own immorality and crime, prate and expatiate upon the increase of crime and laxity of morals due to the leaven of foreign ideas in our body politic. An incident in illustration was given in *The Evening Telegram* one day quite recently. The reporter was going the rounds of the East Side with a sanitary inspector, and in one of the tenement-houses on Orchard Street came across this scene: "On the second-floor there was a poor half-starved child seated in a chair chewing a cracker. A man in the room above said the child was an adopted one. Every week an elegantly attired lady came to see it. He could tell no more than that, but he knew the child was of gentle birth. The doctor found the woman who had charge of the child, and gave her some medicine and a ticket to the Seaside Sanitarium."

One other gift has the baby-farmer who really understands her business that commends her to those desiring her services, and that is the complete obliteration of identity a child undergoes after becoming a boarder. This phase of the industry, it will be remembered, was brought out in the suit of Sivillar Berkely, claiming to be the wife of Forrest S. Downing, for the recovery of her child, who, she asserted, was in the care of a well-known baby-farmer. The evidence in this case was strong on both sides, but as might have been expected was against Miss Berkely. Perhaps under some conditions needless to mention but easy to infer the child might have been shown by testimony to have been other than Carlos Wilson or even Miss Berkely's. An undertaker during this trial testified that forty-five children were buried in coffins precisely alike and the circumstances of burial the same. These conditions surely give little opportunity for future recognition, and there are, and may be, many cases where some certain means of identification are needed, as in the case cited above.

Another model establishment is the one on One Hundred and Sixty-fourth Street, to which the daily newspapers have devoted some attention within the last two weeks. The proprietress of this farm no doubt by this time has a heart swelling with gratitude to the press for placing before the public the unexcelled advantages of the place she presides over. Then there is the "Children's Sanitarium" in New Jersey, near enough to New York to be of some interest. The devoted guardian of this charming retreat is the motherly Christian lady who believes it needless to obtain a permit for burial on the decease of a child. In this case, however, there is some hope of punishment, or Jersey justice will be belied.

Some of the baby-farmers must attain remarkable proficiency in their calling, if they pass through the long experience of the old lady seventy-six years of age, who applied for permission last week from the Brooklyn Health Commissioner to establish a baby-farm. She had been in the business thirty years, and as she was well recommended her desire was gratified.

Still, with the innumerable evils of the system so apparent, it is unjust to say that all the keepers of baby-farms are as heartless as they are pictured. Many, undoubtedly, are even more pitiless than they are painted. From the very nature of the business, the condition of birth, and the youth of the inmates, a large death-rate is to be expected, even in the establishments that have come under public notice. But when to these are added improper food, poor sanitary arrangements, lack of care and proper inspection, it becomes a frightful one. The whole aim of the typical baby-farmer is to make as much as possible with the least expenditure of time, labor, and money. Whenever the domestic economy of one of these places has light thrown upon it there is some show of an investigation. It subsides, however, and is only thought of when another instance comes up. When one of these inquiries is in progress the baby-farmer seeks to impress on the minds of all that she is endowed with every instinct a perfect mother should display toward her child. They give the hearer the same impression he would feel listening to *Madame Frochard* in the "Two Orphans," recounting her love and kindness for the blind girl *Louise*.

As long as society exists under its present conditions it is fair to suppose that baby-farming will be a fixture.

But if it must be conducted, it should be under a stern and rigid inspection, with no opportunity for the escape from punishment of those violating the provisions in regard to it.

SPECIAL DEPARTMENTS IN HOSPITALS.

We have received the first annual report of St. Mary's Hospital, Brooklyn. The report contains some facts that will have an interest to those concerned in hospital management and organization.

The medical and surgical staff numbers no less than thirty-four persons, not including the pathologist and curator. These gentlemen preside over eleven different departments, embracing gynecology, fractures and dislocations, genito-urinary surgery, diseases of the thorax, diseases of the abdominal viscera, obstetrics, neurology, diseases of children, and so on. Each department has its chief and two or three associates. In other words, the cases are divided up very much as is done in the city dispensaries, instead of having simply a medical and surgical service. This decidedly novel plan has now been practically tried for a year, there having been 617 patients treated during the time. Regarding its workings, we cannot do better than quote the words of the report:

"Whatever forebodings, as to the practicability of such an arrangement, may have existed at the outset, and while some without due reflection viewed this new departure with doubt or disfavor, and not a few predicted non-cohesive disaster, the results as set forth in this first annual report will, it is hoped, clearly prove not only its practicability, but that a high degree of co-operative efficiency in the professional service has been effected. The history of each patient on entering the hospital is carefully recorded, and he or she assigned to the appropriate department, after which the head or chief of such department assumes his or her care and treatment, and becomes responsible and, in a measure, accountable to the entire faculty as a supervisory body. In this manner not only is the professional work better and more orderly conducted, and the patient, doubtless, the gainer, but the most perfect harmony exists, and each member of the hospital staff finds his intercourse and association with his colleagues both pleasant and profitable."

Certainly one year's experiment does not settle the question of the real wisdom of this new plan. It will be interesting to study its workings, however, in connection with the entirely opposite method pursued by certain hospitals in this city; as for example Roosevelt, where there is but a single chief surgeon for the whole surgical service.

But it may be inquired now whether the Brooklyn plan is not more just to the patient and physician, and equally fruitful in scientific results.

CONCERNING COMMITMENT TO INSANE ASYLUMS.

The lunacy laws of most communities need overhauling in order to provide proper security against the incarceration in asylums of persons who are not in fact insane. This is true in this country, for there have been within a few years several remarkable instances of unjust commitment through the cupidity or hatred of relatives. The same is true also of England, as will appear from the following statement of a recent litigation, which we take from one of the legal journals: A case of unusual importance is that of Weldon *v.* Winslow, recently tried in the Queen's Bench Division of the English Court, and in which the judgment has been reversed by the full Bench. The action was against Dr. Forbes Winslow, the alienist; it was brought by Mrs. Weldon, whom Dr. Winslow had advised was a proper subject for restraint in an asylum, and whose husband he had aided in endeavoring to put her under such restraint.

The action was for assault and also for libel—the assault being the attempted restraint, the libel being his letter to the husband saying that immediate steps to secure her should be taken; meaning thereby, as plaintiff alleged, that such steps must be taken to put her in confinement as a lunatic.

The doctor relied for his defence as to the assault on an order made on certificates under lunacy statutes; and as to the libel, upon his privilege, as a physician, to write such a letter without malice and in discharge of his duty. Mr. Justice Manisty, in a lengthy opinion, in which Justice Williams concurred, and which will probably soon appear in the current reports, condemned the course of the defendant, who was the proprietor or manager of the asylum to which it was proposed to take plaintiff, for having taken any part in the arrangements for procuring the physicians' certificate, and also criticised the conduct of the physicians, who, instead of making two separate and independent examinations, went together to see her, and, after having an interview together with her, took turns in stepping out, that each might make, what they called, a separate and independent examination.

The Court held that the fact that those steps were taken in pursuance of the plan of sending the plaintiff to an asylum of which the defendant was the proprietor, where he would receive compensation for receiving her, was sufficient evidence of improper motive to require the submission of the case to a jury, and that the Judge at the trial erred in assuming that Dr. Winslow would not be actuated by sordid motives, and dismissing the action for want of evidence to show any improper motive.

The Court evidently appreciated the eccentricity of the plaintiff, for they said that the great difficulty in the argument of the case had been to get at the facts, for the plaintiff, both at the trial and on the argument in the appellate Court, conducted her own case.

But they rightly said that it is not every mere harmless delusion of eccentricity which requires a person to be confined in an asylum.

Few professional positions are more difficult and delicate than those in which a lawyer or physician stands when called upon to advise upon a question of this kind, and to take the necessary steps to secure commitment. The only safe and right course is for those concerned to consult either a medical man, or, better still, a competent lawyer conversant with such subjects; in either case selecting one who has nothing to do with the asylum to which it is contemplated to commit the subject, and to separate entirely the matter of application for commitment from any connection with the subsequent custody and management. The convenience and saving of time effected by relying on the aid of the physician of an asylum for securing commitment, is not worth purchasing at the cost of the mischief which may be involved.

LEPROSY, AND ITS DANGERS.

Good results may follow evil methods, and whether Dr. O'Donnell be a charlatan and an alarmist or not, he has excited interest in a subject that deserves the attention of the American people.

Leprosy is not a disease of which those who are cleanly and chaste need ever have any fear; but as a large number of American citizens possess neither of these virtues, it is well that they provide against the contingency of elephantiasis græcorum. For there is little doubt that leprosy is contagious, just as syphilis is contagious, *i.e.*, through the agency of the secretions and blood. Among licentious people it may spread with rapidity. The influence of heredity is also potent in increasing the number of victims. Lepers reproduce lepers, though fortunately the second generation dies before it can be productive.

The contagion of leprosy, according to Dr. George Thin, lies unquestionably in the *bacillus lepræ*, first discovered by Hansen. This bacillus resembles very closely that of tuberculosis. Its habitat is the lymph or white blood-corpuscle, which it changes into the leprous cell. It makes of this an irritative body, producing the peculiar exudations and low grade inflammatory conditions characteristic of the disease.

The parasitic theory of leprosy is an interesting one, and, if true, would throw a new light upon methods of prophylaxis and treatment. It is difficult, however, to explain satisfactorily by this theory the facts of hereditary transmission of the disease, and especially such a one as is given by Dr. A. W. Saxe. That writer says: The healthy wife of a leper gave birth to a leprous child. Her husband died. The still healthy widow married a healthy man, and gave birth again to a leprous child.

As regards China and leprosy, it is to be borne in mind that, if we are to legislate against the disease, we must not single out China. Leprosy exists also in Mexico, the West Indies, India, Norway, Sweden, New Brunswick, Australia, the Sandwich Islands, Eastern Africa—in fact, on the sea-coast in nearly all tropical regions.

In India there are said to be over 100,000 lepers; the number in China is unknown, but is unquestionably great. The Hawaiians, of all people, are most scourged by it, nearly one-tenth of the population being affected.

Four years ago there were between fifty and one hundred lepers in the United States. Whether this number has increased we cannot say. One thing is certain, however, that the disease cannot be spread by the simple exhibition of cases of leprosy before the public. However bad the taste or useless and sensational the object of such a performance, it would be as innocent to public health as the exhibition of a like number of cases of syphilis.

The citizens of New York who have been so worried over the possible introduction of leprosy into this city, should be informed that for years there have been one or more lepers in the city hospitals, one even having served for a time as a nurse in Bellevue Hospital.

While leprosy is a disease about which much is unknown, there are certain facts that are tolerably well established. These have been formulated by Dr. A. W. Saxe ("Report on Hawaiian Leprosy") as follows:

"1. Leprosy is not a form of syphilis.

"2. It is a specific and well-marked disease.

"3. There are two varieties—the *tubercular* and *anæsthetic* [some add a third, the *macular*].

"4. These varieties may be distinct or associated.

"5. It is more common in males than females.

"6. It is hereditary.

"7. It is contagious.

"8. It is incurable.

"9. Europeans are to a certain extent exempt from the disease, probably from greater precautions in avoiding the contagion.

"10. The causes of the disease are unknown.

"Finally, leprosy disappears with improved hygienic conditions of a people, cultivation of the soil, and absolute isolation of all lepers."

In some cases, we would add, the disease seems to disappear despite the most favorable conditions for its propagation, as has been noted in the Virgin Islands by Dr. Bonn.

THE PROGRESS OF THE CHOLERA.

The reports from the cholera-infected districts show, at date of writing, that the disease is unquestionably decreasing at Marseilles, Toulon, and Arles. On August 3d, for the first time since the epidemic began, no deaths from cholera at Toulon were reported. The number of deaths daily in that city has fallen to an average of three or four, while the cases in the hospitals number about one hundred.

At Marseilles the daily death-rate has varied between seven and twenty-eight. The number of new cases has gradually fallen.

On the other hand, a few cases of cholera have occurred at various places in the neighborhood of the stricken cities, and in several cities and towns in Italy. A case of cholera is also reported to have occurred at Geneva, Switzerland.

The *New York Times* has continued to publish excellent cable reports of the cholera's progress. Consul Mason, of Marseilles, has also given an interesting account of the development of the epidemic. This gentleman writes:

"The present situation may be, therefore, summarized as follows: The epidemic which now prevails at Marseilles and Toulon is Asiatic cholera, imported, beyond all reasonable doubt, from Saigon, China, by the French transport Sarthe, to the port of Toulon. At first the disease was of the type medically classified as 'benign,' but its malignity has since increased by its further diffusion and development under the influence of continued hot weather. At Toulon the epidemic has spread in some degree to neighboring villages, and from Marseilles it has penetrated as far toward the interior as Aix, in Provence. The sea-going commerce of Marseilles is for the time almost entirely suspended. Italy, Spain, Tunis, and Algeria, impose quarantines of from seven to fifteen days upon all vessels from these two infected ports. Ottoman ports absolutely refuse entry to such vessels upon any and all conditions. A strict quarantine of seven days has been established on the land frontiers of Italy and Spain against all persons coming from France; and the conditions of these frontier quarantines

in respect to baggage and merchandise are daily becoming more rigid and exacting. Under these hopeless conditions, nearly all the steamship lines between Marseilles and other Mediterranean and Eastern ports have suspended operations. and have, or will soon, close their offices in Marseilles. On the French island of Corsica no vessel from Toulon or Marseilles is permitted to land passengers, baggage, or merchandise. In Lyons, and at the Paris terminus of the Paris, Lyons, and Mediterranean Railway, all passengers, baggage, and freights, as well as cars coming from Marseilles, are fumigated, disinfected, and subjected to the strictest surveillance."

News of the Week.

Chairs of Hygiene have recently been established at the Universities of Prague and Gratz.

Willard Insane Asylum.—Dr. P. M. Wise has been appointed Superintendent of the Willard Insane Asylum, in place of Dr. Chapin.

A Diagnosis.—"Congestion of the right kidney" is the diagnosis made by his attending physician of an indisposition from which Rev. Henry Ward Beecher has been suffering.

Legislating about Cholera.—M. Paul Bert has proposed in the French Chamber a law which compels every doctor to report without delay the appearance of a case of cholera.

Not in Favor of Women.—The University of Heidelberg has been offered the sum of 100,000 marks on condition that it would admit women to its courses. The offer was refused.

The Summer Sanitary Corps.—During the week ending July 26th the summer corps of physicians visited 5,328 houses and 25,536 families, treated 945 patients, and distributed 2,520 circulars and 1,085 free excursion tickets. Of the diseases treated 463 were diarrhœal, 126 of lungs and throat, and 59 contagious.

Suicide on Account of Headache.—One often hears patients declaring that they will kill themselves if the pains from which they suffer continue. Suicide, simply on account of physical pain, is, however, rare. Recently such a case was reported, the victim having apparently suffered from brain tumor. Only last week we referred to the case of an epileptic who shot himself, because of his incurable affliction.

Cholera and the Migration of Birds.—A cable dispatch says: The fact that the swallows, which migrated from Marseilles at the outbreak of the pestilence, have not yet returned, and that there are no sparrows at all in the city, is adduced as evidence that the atmosphere is still vitiated. This migration of the birds has made a deep impression upon the public mind, and has led to a demand for a purification of the atmosphere by means of bonfires.

A New Treatment for Ulcer of the Stomach.—M. Debove proposes to treat gastric ulcer by practically annulling the function of the stomach. He gives the patient the following dose three times daily: Poudre de viande, 25 grammes; bicarbonate sodæ, 10 grammes. He gives this generally by the syphon tube. In addition he lets the patient drink a litre of milk daily. It is believed that the alkalinized food passes through into the intestines without exciting gastric action.

A New Medical College in the District of Columbia has been organized with the following Faculty: Dr. John T. Winter, Professor of Materia Medica; Dr. Howard H. Barker, Professor of Obstetrics and Dean of the Faculty; Dr. T. E. McArdle, Professor of Surgery; Dr. Samuel F. Adams, Professor of Theory and Practice of Medicine; Dr. G. W. Cook, Professor of Physiology; Dr. G. William West, Professor of Anatomy. The new college is to be called the Medical Department of the "National University."

Static Electricity as a Preventive of Cholera.—Professor R. Vigouroux contributes to *Le Progrès Médical* an article upon the above subject. He refers to the experiments of Boillot, Angus Smith, and Chappuis, which prove the great disinfectant properties of ozone. He then shows that by the static electrical bath upon the insulated stool ozone is disengaged most perfectly and effectively. The electrical bath gives also a stimulus to nutrition which is of importance. Vigouroux concludes that a daily electrical bath on the insulated stool is the best prophylactic against cholera.

An Office Thief.—Dr. A. H. Friedenberg, of this city, writes: "Will you kindly allow space in your journal to warn your readers against another office thief. He is of medium height, slender, blonde, with a smooth face and but a small blonde mustache; he is a German, speaking English fluently, but with a slight accent, well dressed and genteel-looking, and about nineteen or twenty years of age. He follows the same methods as his predecessors in his specialty. He must wait for the doctor, or if that is denied him, he sends the servant on some errand, while he waits in the hall." He managed to steal a microscope from our correspondent.

Ammonia as a Prophylactic against Cholera.—Dr. S. W. Ingraham, of Chicago, writes: "During the years 1865 and 1866 I spent much of my time in New York City, and as the cholera was quite epidemic there during those two years I took occasion to ascertain what class of people were least subject to it. I found that the men who worked in horse stables were rarely, if ever, attacked with the disease, and that their families were less liable to the contagion than persons of other occupations living in the same localities, with the endemic influences nearly or quite equal. Upon special examination I found the clothes and even the skin saturated with ammonia to such an extent that when they came in close proximity to me I could plainly discern its odoriferous properties. From this I was led to believe that their whole bodies were more or less under the influence of the ammonia, and that the cholera contagion would not attach to them."

Doctors and Sanitation.—The following will be read with interest, as it shows, if we mistake not, that it is the plumbers and architects who have been the real sanitary reformers! Says *The Sanitary News*: "The great fault of all medical journals and practitioners lies in this fact, which *The Sanitary News* has often endeavored to point out to their near-sighted or averted gaze, namely, that the most efficient and reasonable sanitary work is accom-

plished by men outside the medical profession. The really useful and valuable sanitary work which conserves the public health is done by these same 'perpetrating' architects and by plumbers, when they design and execute those measures which cheat the physician out of his bill by preventing the causation of disease by defective drainage, etc. What have the medical gentlemen accomplished in their own branch of sanitary work? Have they been able positively to prevent one single disease?" Will not our excellent contemporary the *News* now publish some letters from "A Plumber to a Young Doctor," for example, telling him how to avoid typhoid fever, cholera, small-pox, etc.?

The Waste of the Medical Profession, that is to say the number of annual losses by death and otherwise in Great Britain and Ireland is, according to Sir Lyon Playfair, about 1,600. The *Lancet* denies this and says that the number of deaths annually among the twenty odd thousand British doctors is only about 525, while the number newly registered is over a thousand annually. Applying the same death ratio to the United States the annual loss by death should be between 1,500 and 2,000. The annual additions to the medical ranks, judged by the number of students graduated annually, is over three thousand.

An English Cholera Commission.—The English Government has at last appointed a Commission, consist- of Dr. Klein, F.R.S., and Dr. Heneage Gibbes, to proceed to India and study the cholera. They are expected to act in conjunction with an Indian Cholera Commission also recently appointed. It is gratifying to learn that two such well-qualified gentlemen have been appointed for this important work. Still, although there is a broad field for investigation, one cannot but think that the English Government has been very laggard in appointing the Commission, and that its action now reminds one of locking the stable-door after the horse is stolen.

Scientific Investigation into Cholera.—The physicians of Marseilles have been experimenting with a number of old remedies for cholera, and, as might be expected, with little success. Inhalations of oxygen (and ozone?) seem to relieve dyspnœa somewhat. Intravenous injections of saline solutions have done no permanent good. A Professor Reitsch, heretofore unknown to the scientific world, claims to have accomplished some extraordinary results. He has, he says, successfully inoculated dogs with the cholera bacilli. A correspondent of the *Times* takes the trouble to telegraph across the Atlantic that Professor Reitsch has also discovered a way of studying the cholera microbe alive under the microscope! It is needless to say that this in one of the first things that the discoverer of this microbe himself performed. The same wonderful Professor has discovered an infallible way of determining the severity of an attack in any case by an examination of the dejections. This method he (naturally) keeps secret. We suspect that Professor Reitsch is a humbug, or else is greatly misrepresented by cable.

Cholera and the Temperature.—Simultaneously with the appearance of the first two virulent cases of Asiatic cholera at Marseilles, there began a period of intense sultry heat, which, with the exception of one day, continued till the last of July. On the evening of June 28th, this stifling heat was accompanied by dense swarms of mosquitoes which settled upon the lower part of the city, and were only driven off by fires of pitch and resin, which were lighted along the streets during the night. It is remembered that a similar visitation, accompanied by a similarly dead, stifling atmosphere, had marked the beginning of the great epidemic of 1865, and this circumstance, added to the steady increase of the disease at both Toulon and Marseilles, produced a panic which continued several days. During this period many thousands of people removed to suburban residences or the interior.

The Doctors and the People of the Infected Cholera Districts.—There is no doubt much exaggeration in the dispatches regarding the relations of the people to the doctors in the cholera districts.

One report says: The lower classes dislike and oppose the physicians because they have gotten the notion that the physicians have been instructed to help the cholera along in order to get rid of the surplus population. A paper read by a physician in Berlin lauding the cholera as sweeping off beings unfitted for the struggle of existence, has been widely reproduced in France, and has helped to prejudice the people against the doctors and to confirm them in their belief that the government has adopted views similar to those of the Berlin essayist. An instance of the popular hostility toward the physicians occurred in Marseilles, July 30th. A doctor was going into the slums to attend a patient, when he was confronted by a party of the sick man's neighbors, armed with knives, who chased him away and prevented his ministering to the sufferer.

On the other hand the Municipal Council of Marseilles has resolved to erect, in a prominent place, a tablet to commemorate the noble self-sacrifice of the doctors and Sisters of Charity who were victims of the epidemic. Dr. Patras, who died July 31st, will have a street named after him.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contribu-

tions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—THE MEDICAL RECORD, New York.

Reports of Societies.

British Medical Association.

FIFTY-SECOND ANNUAL MEETING,

Held in Belfast, Ireland, Tuesday, Wednesday, Thursday, and Friday, July 29, 30, 31, *and August* 1, 1884.

(BY CABLE TO THE MEDICAL RECORD.)

(Concluded from page 132.)

THURSDAY, JULY 31ST—THIRD DAY.

THE Council met from 9.30 A.M. to 11 A.M. when the General Session was called to order by the President.

THE ADDRESS IN PHYSIOLOGY

was then delivered by PETER REDFERN, M.D. (*vide* page 113). This was listened to with marked attention by a large audience. At the conclusion a vote of thanks was tendered the orator.

THE REPORT OF THE MEDICAL REFORM COMMITTEE

was next presented, and after some discussion was adopted.

THE MEDICAL ACT AMENDMENT BILL

was brought up and discussed by Drs. Waters, Stokes, Brown, O'Connor, and others. The general sentiment was against such amendments as has been made by those really opposed to the measure. The ostensible intention of the latter parties was to thus impede its passage. The main objects of the bill are the adequate representation of the profession in the Council, the provision for an uniform qualification for the *Register* and the maintenance of safeguards against the assumption of illegal professional titles. This bill was finally endorsed.

After the transaction of some miscellaneous business the Association then adjourned until Friday.

FRIDAY, AUGUST 1ST—FOURTH DAY.

The meeting was called to order at 10 A.M., when the

ADDRESS IN OBSTETRIC MEDICINE

was delivered by DR. GEO. H. KIDD (see p. 141).

At the 2 P.M. session the Reform Committee's report was reconsidered and again presented, and the points therein discussed by various speakers.

The reports of the various committees were then presented and adopted, after which the Association adjourned.

REPORTS OF SECTIONS.

SECTION ON SURGERY.

THURSDAY, JULY 31ST—THIRD DAY.

The Section was called to order at 2 P.M. by the President, SIR WM. MCCORMAC.

No address on surgery was delivered.

TRANSPORT SPLINT.

MR. JOHN FAGAN demonstrated his transport splint, and also exhibited some cases upon which excision of the knee had been performed.

NEW ELASTIC TOURNIQUET.

DR. J. WARD COUSINS showed a new elastic tourniquet and explained his mode of application as well as its adaptability to a large range of cases. Its principal claims were simplicity and efficiency.

SECTION ON PUBLIC MEDICINE.

THURSDAY, JULY 31ST—THIRD DAY.

The Section was called to order by THE PRESIDENT, who delivered his address, taking for his subject the

GENERAL CHARACTER OF EPIDEMICS.

In the course of his remarks he referred to the prevalence of cholera on the Continent, and urged due vigilance on the part of the profession and Government of Great Britain against the invasion. Nothing was of more importance than the purification of the drinking-water, attention to perfect sewerage, and the free use of disinfectants. In fact, the purer the water of a district the lower was the death-rate. The labors of Pasteur, Budd, and Koch were appropriately referred to and eulogized.

SECTION ON MEDICINE.

THURSDAY, JULY 31ST—THIRD DAY.

The chair was occupied by the President, DR. J. W. T. SMITH, of Belfast.

THE CAUSATIVE RELATIONS OF PHTHISIS,

was introduced by DR. DOUGLAS POWELL. His line of argument was against the contagiousness of the disease.

DR. J. WARD COUSINS disputed such an assumption, and exhibited an antiseptic inhaler, which he claimed to be efficacious in killing the infecting bacilli.

PROFESSOR GARDINER spoke in support of Koch's views in regard to contagion.

DR. DYCE DUCKWORTH presented the subject of "Rheumatoid Arthritis."

SECTION ON PHARMACOLOGY AND THEURAPEUTICS.

DR. SHOEMAKER, of Philadelphia, presented the subject of

OLEATES,

and urged a further investigation into their nature and action.

SECTION ON OBSTETRIC MEDICINE.

WEDNESDAY, JULY 30TH—SECOND DAY.

THE PRESIDENT of the Section, after calling the meeting to order, delivered an address in which he defended the rights of obstetric men to operate, contending in that connection that no men could be competent gynecologists who were not surgically inclined.

Saturday was occupied in excursions to Giant's Causeway, Garron Tower, Newcastle, and other points of interest.

About six hundred members were present at the meeting.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twentieth Annual Meeting, held July 16th and 17th, at the Grand Hotel, Catskill Mountains, N. Y.

FIRST DAY—WEDNESDAY, JULY 16TH—MORNING SESSION.

In the absence of the President, DR. W. F. NORRIS, of Philadelphia, presided.

Dr. O. F. Wadsworth, of Boston, was elected to fill the vacancy caused by the resignation of Dr. Richard H. Derby, Secretary and Treasurer.

The first paper was entitled

IRIDECTOMY IN CHRONIC IRITIS,

by DR. HASKET DERBY, of Boston.

A case in which frequent attacks of iritis had occurred was described. The patient had obtained relief from the use of atropine. She finally passed into the hands of another surgeon who diagnosed glaucoma and performed iridectomy. After this the attacks of iritis became less frequent. The doctor, however, thought that the improvement was to be attributed more to the natural tendency of the disease to wear itself out than to any good effects of the operation, and concluded that under these circumstances an operation was not justifiable.

DR. H. KNAPP, of New York, stated that in many instances recurrent iritis stops spontaneously. He would restrict the operation of iridectomy to those cases in which with the iritis there is a tendency to cyclitis and glaucoma. In genuine iritis he does not recommend the operation.

DR. CHARLES S. BULL, of New York, read a paper entitled,

CASES OF RESTORATION OF THE EYELID BY TRANSPLANTATION OF FLAP WITHOUT A PEDICLE BY WOLFE'S METHOD.

Two cases were reported in which the upper lid was the one operated on, the flap being taken from the front of the fore-arm, and after being deprived of all subcutaneous tissue, being placed on the denuded lid, and, when necessary, held in position with sutures. The dressing consisted of gold-beaters' skin, with iodoform gauze, borated cotton, and a bandage. This dressing was left undisturbed for three or four days. After this the dressing was repeated every day, or every other day.

In the third case the lower lid was operated on, the flap being taken from the anterior surface of the chest. In those cases in which sutures were applied, there was a little suppuration at their seat, but in all the cases a satisfactory result was obtained.

DR. B. E. FRYER, U. S. Army, then reported

A SUCCESSFUL CASE OF SKIN TRANSPLANTATION WITHOUT A PEDICLE TO THE LOWER LID AFTER REMOVAL OF AN EPITHELIOMA.

In this case, after removal of the epithelioma by excision, a flap was taken from the fore-arm and applied to the raw surface of the upper lid. No sutures were applied, but the flap was held in position with gold-beaters' skin plaster. Two layers of this were applied and allowed to dry. It was then found that they kept the edges of the wound in perfect apposition. The lids were stitched together with fine silk sutures. As the patient in returning to her home would be exposed to cold, a pad of absorbent cotton was applied to protect the part. This was removed on the arrival of the patient at her home. On the eighth day the plaster was removed, and perfect union found to have occurred. Three months after the operation there had been but slight contraction. The doctor laid particular stress on this method of dressing these wounds. If the operation were done at the patient's house he would dispense with the pad of cotton.

CASE OF GANGRENE OF THE LID WITH SUBSEQUENT RESTORATION OF TISSUE WITHOUT A PLASTIC OPERATION.

DR. RICHARD H. DERBY, of New York, reported a case which, when first seen, was found to have marked gangrene of the lower lid. The case then passed from observation, and was not seen for four weeks. When he returned, it was found that the skin had restored itself and that there was very little deformity.

The discussion of these papers was entered into by Drs. Pooley, Prout, Harlan, Little, Howe, Andrews, Lippincott, Fryer, Green, and Wadsworth.

HYSTERICAL MONOCULAR BLINDNESS, WITH MYDRIASIS AND BLEPHAROSPASM,

was the title of a paper read by DR. GEORGE C. HARLAN, of Philadelphia.

A case of monocular blindness was described, in which it was accidentally discovered that the blindness, as well as the spasm of the face which was present, was much benefited by the application of a Charcot magnet. A piece of wood made to imitate the real magnet was prepared, and with this the same results were obtained The patient afterward presented herself with an hysterical affection of the elbow-joint, which was also relieved by the imitation magnet.

DR. H. KNAPP, of New York, read a paper entitled

NEURO-RETINITIS WITH FULMINANT BLINDNESS.

CASE I.—An apparently healthy man, after a day of severe headache went to bed and slept well, but the following morning on awakening found that he could see with neither eye. In the absence of any other adequate explanation, the blindness was attributed to uræmia. Examination of the urine, however, failed to reveal any abnormality. The diagnosis of uræmic blindness was concurred in by a number of prominent physicians. Examination of the eye showed well-marked choked disks. The treatment consisted in the induction of perspiration with salicylate of sodium, and the subsequent use of iodide of potassium and calomel. After the lapse of some time, the islet of retinal tissue regained its functional activity, and the man could see objects held in a certain position, provided they were not brought too close to the eye. He could thus read Snellen 50, and could correctly indicate the names of playing-cards. The doctor thought that the attack might be attributable to some abnormity about the frontal lobes of the brain in the region of the chiasm.

CASE II.—A girl eleven years of age had had spells of loss of vision for a few days, after which she awoke one morning to find herself blind in the left eye. The right also became blind in the course of the same day. The urine was normal. Salicylate of sodium and calomel were given. This was followed by profuse diarrhœa. Two days later there was light perception, and steady improvement set in from this time. Two months later the eye-sight was completely restored. It was thought that there might be something causing pressure in the neighborhood of the optic chiasm or cavernous plexus. If there were such a condition the diarrhœa which was induced would be of benefit.

DR. CHARLES KIPP, of Newark, N. J., referred to a case of choked disk which he had had under observation for fifteen years and in which no symptoms of brain or other trouble had been observed. He thought that probably in some instances optic neuritis was due to other than cerebral lesions.

DR. H. KNAPP called attention to the fact that disease of the frontal lobes might exist for a long time without producing alarming symptoms.

DR. GEORGE C. HARLAN, of Philadelphia, stated that he had examined a number of patients in blind asylums, with atrophy of the optic nerve, without finding any evidences of serious disease.

Dr. A. Alt, of St. Louis, had seen a case of neuro-retinitis with large hemorrhage, which was thought to be due to a tumor of the brain and with marked impairment of the general health. Under the use of iodide of potassium the health was restored. There is, however, atrophy of both optic nerves.

Dr. W. F. Norris, of Philadelphia, read a paper on

HEREDITARY ATROPHY OF THE OPTIC NERVE.

In a family of twenty-three persons which had been examined by Dr. Norris, fourteen were found to have congenital atrophy of the optic nerve. Bichloride of mercury and strychnia were administered, but in only one case did improvement ensue.

Dr. Norris also reported

TWO CASES OF ORBITAL TUMOR.

The first case was one of myxo-sarcoma of the orbit occurring in a child four months old. The tumor was twice removed, but returned after both operations. In the second case, the tumor was an osteoma, which appeared in a woman thirty-two years of age. The growth involved so much of the orbit, that it became necessary to remove the eye. This eye had been blind for some time. The tumor was chiselled away. There has been no return of the disease.

Dr. J. A. Andrews, of New York, read a paper on

JEQUIRITY.

He objected to the plan usually followed in the use of this drug. His method is to employ a one per cent. fresh solution, which is brushed over the eye once. The eye is examined after twenty-four hours and the application repeated, if necessary. In this way he has had good results with no accidents.

Dr. Norris had observed that the conjunctiva seems to lose its susceptibility to the action of the drug after frequent applications.

Dr. H. S. Schell had used preparations which had been preserved for weeks by the addition of four grains of boracic acid to each ounce of the infusion.

Dr. Wadsworth had preserved the infusion active and free from bacilli with the addition of two per cent. of carbolic acid.

Dr. J. S. Prout stated that he had used quinine a number of years ago in the class of cases for which jequirity was recommended. It had produced very satisfactory results.

Adjourned.

AFTERNOON SESSION.

The Society again met at 4 P.M., to examine a number of microscopical specimens prepared by Dr. A. Alt, of St. Louis, and to witness the demonstration of a new form of perimeter by Dr. E. Dyer, of Newport.

EVENING SESSION.

The Society was called to order at eight o'clock.

The first paper was read by Dr. H. S. Schell, of Philadelphia, on

EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.

An old lady suddenly lost vision in the left eye. There was found to be on examination insufficiency of the mitral valve and hypertrophy of the left ventricle. Special attention was called to the fact that after massage of the eyeball a current was induced in the vessels, but this current, instead of being continuous, was broken into segments. No benefit followed treatment.

Dr. A. Mathewson, of Brooklyn, then read a paper on

THE NATURAL HISTORY OF CATARACT.

A man who had suffered from cataract for some years suddenly regained vision. An examination of the eye showed that the lens had disappeared, and it was afterward found in the lower part of the vitreous. Two years later a severe attack of glaucomatous inflammation required the removal of the eye. The lens was found to be extremely small.

Other members reported cases of a similar character.

Dr. W. W. Seely, of Cincinnati, described his experiences in certain refractive cases, alluding particularly to lack of balance of the ocular muscle and its relation to refractive changes. He thought that if all cases of so-called mixed astigmatism were examined after paralysis of the accommodation, many of them would be found to be examples of simple hypermetropic astigmatism. A number of illustrative cases were cited.

Dr. L. Webster Fox presented a paper on

THE CLINICAL HISTORY OF A CASE OF SYMPATHETIC OPHTHALMIA.

A boy received a punctured wound near the cornea of the left eye. It was treated with cold applications and little inflammation ensued. Later, however, dimness of vision manifested itself in the right eye. At this time there was barely light perception in the eye. Vigorous treatment was instituted, but did not abort the inflammation. Later, iodide of potassium and mercury were administered, but with no benefit. A recent examination showed the right eye atrophied to half its normal size, with no perception of light, and the left eye, becoming atrophied, light-perception doubtful.

Dr. J. A. Lippincott, of Pittsburg, Pa., read a paper entitled

TWO CASES OF ORBITAL ABSCESS.

The first case occurred in the latter part of 1877 in a child of feeble powers of resistance, and the abscess followed an attack of erysipelas of the face and scalp. A small abscess of the right upper eyelid developed, which was opened and a poultice applied. Six days later the eyeball began to protrude rapidly and the pain and general symptoms became more marked. The ball protruded more than half an inch. Diplopia was observed and the sight appeared to be unimpaired.

An exploratory incision was made under ether, and pus being found a free incision was made, allowing the escape of a quantity of pus. It was decided to not insert a tent, but a poultice was applied, pressure made, and a supporting treatment instituted. Under this treatment the patient improved, and the protrusion became less marked. Two days after the operation on the right eye it became necessary to open an abscess behind the left ball. This rapidly healed without further treatment. An examination made a short time ago showed very slight protrusion of the right eye. $V = \frac{20}{XX}$.

Case II.—A. R——, scarcely twelve months old, was seen in the latter part of 1880. Swelling and chemosis of the lids had appeared three weeks previously. There was no protrusion of the ball until a few days before she was seen by Dr. Lippincott. At that time the ball protruded to the extent of its diameter, the pupil was of natural size and irresponsive. The pain did not seem to be severe and there was only slight fever.

An aspirating needle was introduced above the globe and an abscess containing fetid pus was found; this was evacuated and a poultice applied. Improvement of the general condition at once began, but one week later the opening closed, and as there evidently was pus still behind the globe, a second opening was made, and at this time healthy pus escaped. Pus continued to flow for two weeks when the opening closed. The child continued to improve, and a recent examination showed very little protrusion of the ball, considerable swelling of the lids, and partial ptosis. The eyeball is freely movable. The disk shows decided white atrophy, and the vessels of the retina are contracted. Vision is limited to light-perception.

Dr. Samuel Theobald, of Baltimore, described a case of this nature, which he had recently seen occurring

in a man run down from over-work. Four days after the beginning of the symptoms deep fluctuation was felt, and the abscess was opened. Poultices were then applied. Two days later it was found necessary to evacuate a collection of pus which had formed beneath the ball. Perfect recovery followed, the vision being restored, and the mobility being normal.

Dr. Charles J. Kipp, of Newark, read a paper on

ABSCESS OF THE FRONTAL SINUS, ETHMOID CELLS, AND SPHENOIDAL SINUS.

J. B——, aged fifty-four, had suffered for many years from headache. The left eye was slightly protruding, and a tumor was seen involving the upper part of the orbit. Sarcoma was diagnosed, but a few days later, in attempting to remove it, the swelling broke, and a large quantity of pus escaped. A drainage-tube was introduced. Shortly after the operation the patient had pneumonia, from which he died. After death it was found that the frontal sinus, the ethmoidal cells, and sphenoidal sinus had been converted into one large pus cavity, from the walls of which numerous spicules of bone projected.

Dr. Kipp also reported a case of distention of the frontal sinus. A woman, aged fifty-seven, presented a painful tumor below the left eyebrow. She had suffered from naso-pharyngeal catarrh for a number of years. On pressure, fluctuation could be discovered. An operation was declined. The case was seen one year later, at which time the sac accidentally ruptured, and the contents escaped into the nose. The cyst continued to refill for some time, but after some months the discharge diminished, and at the present time the sac seldom becomes distended. The treatment consisted in the application of nitrate of silver solution to the mucous membrane of the naso-pharynx, the frequent washing-out of the nasal cavity, and the emptying of the distended frontal sinus by pressure made with the finger.

Dr. L. Howe, of Buffalo, read a paper entitled,

CHANGES IN THE EYE IMMEDIATELY AFTER DEATH.

The observations were made on a man, aged fifty-four, dying of consumption. One of the conditions noticed was a wrinkling of the cornea, which it was said might readily be mistaken for fracture rupture of the lens. He had also seen the same condition after hanging.

Dr. Norris asked whether any rose-colored macula had been observed after death by hanging. These had been observed in the case of beheaded criminals.

Dr. Howe had observed none.

Dr. Mittendorf called attention to the fact that Dr. Derby had made a report some time ago in reference to the condition of the eyes after hanging. In six eyes examined, in five dislocation of the lens had been observed.

Adjourned.

Second Day—Thursday, July 17th—Morning Session.

CASE OF GLIOMA OF THE RETINA.

Dr. Theobald reported a case of glioma in which he enucleated the eye four years ago. The patient is still under observation and there has been no return of the disease. In another case he had performed the operation. Twelve months later the patient died from some obscure disease of the brain. There had been no return of the glioma. The age of the first case was twelve years, that of the second nine years.

Dr. Mittendorf asked if any of the members had seen a case of glioma in which the patient did not die after operation. Although the operation prolongs life, he thought that it did not save it. It was unusual for the disease to develop as late as in the cases reported by Dr. Theobald.

Dr. Sutphen, of Newark, reported a case of glioma in a child nine years of age. Enucleation was advised, but declined. Five months later the child was brought suffering with choreic symptoms. Thinking that the chorea was due to the eye trouble it was enucleated. The child recovered while taking Fowler's solution.

Dr. Mathewson thought that some of the rare cases in which the disease had not returned after operation might be accounted for by a mistake in the diagnosis.

Dr. Knapp said that there could be no doubt of permanent recovery occurring after true glioma. These cases are, however, rare. In his own experience he had had but one case. This had been under observation for fourteen years.

Dr. William Thompson, of Philadelphia, made a partial report of the progress of the examination of the employees of the Pennsylvania Railroad as to their color-sense and acuteness of vision and hearing. He also considered the importance of national legislation on this subject, and described what had already been done in this direction.

Dr. George C. Harlan reported

TWO CASES OF SWELLING OF THE OPTIC PAPULE, PROBABLY CONGENITAL.

The first case was that of a short-sighted student, who consulted Dr. Harlan in reference to glasses that he was wearing. An ophthalmoscopic examination which was then made showed that there was swelling of the optic papule to the extent of 3 or 4 D. He was advised to be cautious in the use of the eyes. The case was seen subsequently, but no change was noted.

The second case was that of a girl aged fifteen years. She complained of pain in the eyeball, increased by use, and occasional double vision in a vertical direction. There was hypermetropia, and also swelling of the optic papule. Weak convex, slightly smoked glasses were given. With this the vision was $\frac{20}{20}$. A tonic treatment was instituted. The patient sood afterward passed from observation, and has not been seen since.

Dr. Risley reported the case of a young married woman who consulted him for asthenopic symptoms. There was found to be hypermetropic astigmatism and swelling of the nerve to the extent of two or three dioptrics. The condition was the same in both eyes. There had been no dizziness and no more headache than could be accounted for by the eye-strain. There was nothing abnormal about the urine. The proper glasses being given the symptoms disappeared, and a year later had not returned. There had at this time been no change in the appearance of the eye.

Dr. Mittendorf also reported a case of hypermetropic astigmatism with a similar condition of the nerve. He attributed this appearance to an abnormal development of the connective tissue elements of the optic disk. This view was held on account of the silky appearance of the retina. This case had been under observation for over a year.

Dr. G. Hay, of Boston, reported

TWO CASES IN WHICH RAHLMAN'S HYPERBOLIC LENSES IMPROVED VISION.

The first case was that of a lawyer, in whom the cornea was decidedly prominent. Vision was improved by a cylindrical glass, but it was made still better with hyperbolic lenses.

The second case was one of pronounced conical cornea. In this case also vision was much improved.

Dr. O. F. Wadsworth, of Boston, read a paper on

MYXODERMA, WITH ATROPHY OF THE OPTIC NERVES.

The patient was a married woman, forty-two years of age. There was no history of syphilis. Menstruation had been regular until three years ago, when it ceased. Six years ago it was noticed that the lower part of the face, the hands, and the feet became full and œdematous, but did not pit on pressure. This condition increased. At the present time the hands and feet are very much enlarged. The lower part of the face and,

what is unusual, the nose is much enlarged. The lips are thick and the speech is slow, as though the tongue were enlarged. The skin is not particularly dry, but she never sweats. Her mental condition is good, although her husband thinks that her memory is not as good as formerly.

The affection of vision was first noticed in the right eye a year and a half ago. This gradually increased until there was only light perception. In the left eye vision was $\frac{20}{XX}$. The field was contracted upward and outward. The optic disks, especially that of the right eye showed the appearances of simple gray atrophy. No apparent cause could be discovered for this condition. The fact that the atrophy appeared in the course of the myxoderma did not prove that there was any connection between the two, but considering that our knowledge of the cause and pathology of myxoderma is so incomplete he thought it well to place this case on record. He had examined other cases of myxoderma, but this was the only one in which any alteration of vision had been observed.

Dr. Little had also examined the eyes of those suffering with this affection, but had been unable to find anything abnormal.

Dr. Thomas R. Pooley, of New York, read a paper entitled

ACUTE DACRYO-ADENITIS,

A girl, twenty years of age, who for some time had been suffering with chronic trachoma and trichiasis, was seized with diphtheritic inflammation of the conjunctiva of the left eye. This caused the complete destruction of the eye. Three weeks later, when the purulent discharge was beginning to abate, pain began to be felt in the right eye and a swelling made its appearance at the upper outer angle. This was tense and red. Hot applications were ordered and she was put on the use of quinine and iron. The following day an incision was made through the lid, but no pus was obtained. The following day there was marked improvement. The hot applications were continued and a pressure-bandage applied. She made a rapid recovery, and now vision is entirely restored. It was thought that probably the inflammation of the lachrymal gland was due to septic absorption.

Dr. H. Knapp, in speaking of the differential diagnosis, said that the diagnosis could be made by pressing deeply into the orbit. It would then be found that the swelling was limited to the gland, and that it gave a nodular sensation, some of the nodules being harder than others. It is not very rare to have inflammation of one lachrymal gland, but it is rare to have the inflammation appearing in both glands within one or two days. In the cases which he had seen there had been no infectious disease, and in the majority no conjunctival trouble.

Dr. Miller, of Providence, stated that he had had one case of acute bilateral inflammation of the lachrymal gland. The patient was suffering with gonorrhœa at the time and his physician regarded it as a case of gonorrhœal ophthalmia. The inflammation subsided in the course of a few days under the use of hot applications.

Dr. W. F. Mittendorf, of New York, read a paper on

POLYCORIA.

The patient, Miss R——, sought advice for some abnormity of vision. Seven years previously the right eye had been lost. There was compound myopic astigmatism in the left eye. On examining it five pupils were found. With suitable glass V. = $\frac{20}{XX}$, and the range of accommodation was good.

The father of this lady also had a similar defect in the iris. In the right eye there were two pupils, the lower of which was divided into two by a band passing across it.

Dr. W. W. Seely, had examined a family in which a number of its members had polycoria. The interesting point was the termination, all these persons becoming blind.

Dr. Mittendorf stated that his patients were aged thirty-two years and sixty-five years, and that neither had exhibited any indication of failing sight.

Dr. E. Hutchinson, of Utica, described

A PLASTIC OPERATION PERFORMED TO RELIEVE THE CLOSURE OF THE LIDS, THE RESULT OF CICATRIZATION.

The man had his face injured by the premature explosion of a blast. This caused destruction of the left eye, and such contraction of the lids of the right eye that it was impossible for him to open them. The sight of the right eye was uninjured. The operation consisted in cutting deeply through the external commissure, then dissecting up a web of conjunctiva which was put into this opening and secured there. After he had recovered from this operation there was great ectropion, which was relieved by making a deep V-shaped incision and free dissection and bringing the parts together. The lid was thus restored and a very satisfactory result obtained.

Dr. J. Aub, of Cincinnati, read a paper on

REMOVAL OF FOREIGN BODIES FROM THE VITREOUS.

He reported three cases in which pieces of iron had entered the vitreous humor. In all of these the piece of iron was removed by means of an electro-magnet passed into the eye. In these cases the eye and the sight were saved.

A fourth case was reported in which the piece of iron had become encysted and could not be removed with the magnet. In this case it became necessary to enucleate the ball, and after the removal of the eye it was found impossible to remove the foreign body with forceps before cutting the lymph which surrounded it.

Dr. Knapp said that where a foreign body can be seen, it is usually not a difficult matter to remove it, the question was as regards those cases in which it passes out of sight. He had in one case succeeded in removing the foreign body. He felt inclined to say, judging from his own experience and the recorded experience of others, that those cases in which the foreign body enters the eye and passes out of sight, the best thing to do would be to enucleate the eye. In this way he thought that the greatest good would be done to the greatest number.

Dr. Mittendorf, agreed in this opinion.

HYPERMETROPIC ASTIGMATISM PASSING INTO MYOPIA,

was the title of a paper by Dr. S. D. Risley, of Philadelphia. In 1875, he had seen a child suffering from violent headache. There was hypermetropic astigmatism. The ophthalmoscope revealed the usual appearances of choroidal and retinal irritation. With a suitable cylindro-spherical glass vision was normal. This entirely relieved the symptoms. The patient passed from observation and was not seen until 1882. At this time there was found to be myopic astigmatism. The proper glasses being given, the symptoms from which she had suffered disappeared and vision was again made normal.

Dr. Knapp thought that many of the cases of astigmatism in young girls of nervous temperament were not real deformities of the cornea, but that they would disappear under proper hygienic surroundings. He thought that slight degrees of error might be overlooked.

Dr. Theobald said that the indication for correction in slight degrees of myopia was the presence of asthenopic symptoms, which are sometimes due to disproportion between accommodation and convergence. In slight degrees of myopia, where there is no asthenopia there is no discomfort, and correction may not be necessary.

The Society then went into executive session.

The following officers were elected: *President*—Dr. W. F. Norris, Philadelphia; *Vice-President*—Dr. Hasket Derby, New York; *Recording Secretary and Treasurer*—Dr. O. F. Wadsworth, Boston; *Corresponding Secretary*—Dr. J. S. Prout, Brooklyn; *Committee on Publication*—Drs. O. F. Wadsworth, Hasket Derby, and G. Hay; *Committee on Membership*—Drs. John Green, G.

C. Harlan, A. Mathewson, S. Theobald, and J. J. B. Vermyne.

The following were elected to membership: Dr. Miles Standish, of Boston, Mass.; Dr. John Van Duyn, of Syracuse, N. Y., and Dr. S. O. Richey, of Washington, D. C.

The place for holding the meeting of next year was not decided on, but its selection left to the secretary. The time of meeting is the third Wednesday of July.

The Society then adjourned.

THE SURGICAL SOCIETY OF PARIS.

Stated Meeting, June 4, 1884.

M. Marcus Sée, President, in the Chair.

(Special Report to The Medical Record.)

After the Society had been called to order, the report was read of the committee for the organization of an

ANNUAL CONGRESS OF FRENCH SURGEONS.

This report gave rise to a lengthy discussion.

M. Boeckel then read the history of a case operated upon by himself for the

REMOVAL OF THE ENTIRE UTERUS PER VAGINAM

on account of cancer of the cervix. The operation was undertaken in October, 1882. After pushing the uterus as far down as possible, the posterior cul-de-sac was divided by a transverse incision, and the anterior part dissected away, so as to leave the organ attached only by the broad ligaments. A double ligature being placed on each, the ligaments were then divided. In the left broad ligament M. Boeckel found an enlarged and degenerated gland, which he excised. This was followed by a free hemorrhage, which was arrested by hæmostatic forceps applied somewhat at random and left *in situ*. As the intestines showed no tendency to come out through the wound, no sutures were passed through the peritoneum. The vagina was tamponed with cotton dusted with iodoform.

The patient seemed to be making a good recovery, until it was found that the urine was constantly passing away from a wound made in the left ureter by the hæmostatic forceps. The only remedy for this condition seemed to be

NEPHRECTOMY,

which was accordingly performed. The patient recovered promptly, and was discharged cured two weeks after the last operation. Seven months later, however, she died from cancerous infiltration of the vaginal walls and the neighboring glands.

From a study of this case M. Boeckel concluded that: first, the antiseptic method renders justifiable the undertaking of very serious operations; and, second, the total extirpation of the uterus should be considered an exceptional operation, to be undertaken only when the cancerous infiltration is localized.

M. Verneuil agreed with the author that hysterectomy ought to be undertaken only in exceptional cases. He thought that the treatment of carcinoma of the uterus by cauterization and local applications gave the best chance to the patient.

M. Terrier had recently performed this operation, and spoke of the difficulties attending it. One of the greatest of these is met with in pulling down the broad ligaments, so as to permit the application of the ligatures.

M. Polaillon did not agree with the author of the paper regarding the indications for the operation. He would operate only in those cases in which the entire organ, and not the cervix alone is involved in the cancerous process. But if the new growth has advanced very far no operation is of any avail.

M. Lucas-Championnière had seen Billroth perform the operation in a case in which one of the broad ligaments was involved in the carcinomatous degeneration, and was surprised at the ease with which the removal of the organ was accomplished. The main difficulty he thought was one of diagnosis.

M. Terrier did not agree with M. Polaillon, but advocated the removal of the entire uterus. He thought that the attempt to destroy the new growth by the galvano-cautery and chloride of zinc was not unattended with danger.

M. Trélat did not think the results obtained in the past seven years by extirpation of the uterus were such as to offer much encouragement. He himself had never had the courage to attempt it. Indeed, he thought there was little to hope for in any operation, as by the time that the patient fell into the surgeon's hands the disease was usually very extensive.

M. Bouilly was convinced, from experiments made upon the cadaver, that it was often impossible to depress the uterus sufficiently to render the vaginal operation practicable.

M. Polaillon stated, in support of his opinions, that the mortality in total extirpation of the uterus was one in three, while that from removal of the cervix was three in twenty. He had had two cases of removal of the new growth by the galvano-cautery and chloride of zinc, in which there was no return of the disease after five years. Another patient, seventy-two years of age, operated upon by the same method, had remained well for one year.

M. Boeckel then exhibited a patient, seventeen years old, upon whom he had performed

OSTEOTOMY BY MACEWEN'S METHOD

for knock-knee. He had performed upward of twenty osteotomies and nearly as many osteoclasies. The results of osteotomy were uniformly good, but he had met with three accidents in his osteoclasies. In one case he had ruptured the external lateral ligament; in another, a suppurative periostitis had been excited which required four months to cure; and in the third case there remained an incurable pseudarthrosis.

The Society then adjourned.

Stated Meeting, June 11, 1884.

The Society having been called to order, the

DISCUSSION ON VAGINAL HYSTERECTOMY

was resumed.

M. Verneuil stated that he had performed ablation of the cervix twenty times, twice for hypertrophy of the anterior lip, once for sclerosing metritis, which he had mistaken for an epithelioma, and seventeen times for cancer. Of the latter cases one had died and two had been lost sight of after three years had elapsed without return of the disease. Of the remainder the average duration of life after the operation was nineteen months. The speaker did not condemn the total extirpation of the uterus, but he considered that the existence of a limited epithelioma of the cervix was not a sufficient indication for the operation.

M. Desprès had removed the cervix seven times, three times for hypertrophy of the anterior lip, and four times for cancer. He did not think that an operation was of much value in prolonging life, for the average duration of life in those not operated upon was eighteen months. When the general condition was bad, life was prolonged not one hour by the removal of the new growth.

M. Trélat was surprised that M. Verneuil should have had so many opportunities to practise amputation of the cervix, since the patients usually present themselves to the surgeon only after the disease has progressed too far to render this operation of any avail. He was in accord with that gentleman in respect to the methods of treat-

ment employed, and he believed that these methods were the best adapted for prolonging life. He had seen patients gain flesh and be restored to apparent health under this treatment of the local affection.

M. BERGER then made a report upon a memoir submitted by M. Kirmisson entitled

INGUINAL ANEURISMS.

The author stated that the appearance of an aneurism in the groin is often preceded by an abscess or enlargement of the inguinal glands. Malgaigne and others had already noted this fact. As regards the treatment, M. Kirmisson expressed a decided preference for

LIGATURE OF THE EXTERNAL ILIAC ARTERY

over either mechanical or digital compression. Of the four methods at present in vogue he would retain two, those of Sir Astley Cooper and Marcellin Duval. The procedures introduced by Bogros and Abernethy he looked upon as dangerous. The author did not regard the wounding of the peritoneum as a serious complication, but on this point M. Berger differed from him very decidedly, and he insisted upon the necessity of laying aside the bistoury as soon as the aponeurosis of the obliquus externus had been divided. Secondary hemorrhage, when it occurred, was to be attributed, M. Berger thought, to non-uion of the wound and to suppuration.

M. VERNEUIL did not agree with M. Berger as to the cause of secondary hemorrhage. It was due, he believed, to septicæmia. When there was no fever there was no cause to anticipate hemorrhage.

M. DEPRÈS, while believing with M. Verneuil that septicæmia was a common cause of secondary hemorrhage, thought that the accident was not less frequently due to mechanical causes.

M. FARABŒUF showed the excellence of Cooper's operation, by which the artery is reached most surely and by the shortest path. He agreed with M. Berger that no cutting instrument should be used after the division of the aponeurosis of the external oblique muscle had been accomplished.

M. TERRIER related a case of

EXTIRPATION OF THE SPLEEN,

and exhibited the organ removed, which weighed a little over thirteen pounds. The patient was suffering from a slight degree of leucocythæmia, the examination of the blood showing a proportion of one white to two hundred and seventy-five red globules. The operation was successfully completed, but the patient died twenty hours afterward from capillary hemorrhage into the peritoneal cavity. The result in this case, the speaker thought, lends confirmation to the views of those who refuse to perform any operation upon the subjects of leucocythæmia. Such operations are nearly always fatal, though an Italian surgeon has reported one successful case in which the proportion of white to red corpuscles was as one to thirty.

The Society then adjourned.

THE QUESTION OF TYING THE UMBILICAL CORD AFTER LABOR.—Dr. John T. Booth, of Wyoming, O., relates the history of a case where an illegitimate child was born and the cord was cut but not tied. The probable object was to let the child bleed to death. Instead of this it did well, there being no hemorrhage at all. Dr. Booth raises the old query whether tying the cord is necessary. Some have claimed that it is not, and undoubtedly in many, if not in most cases, there will be no hemorrhage if the physician wait till the child has breathed a few times. But the present practice of tying is a safe and wise one.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEDICAL BILL AND ITS CHANCES—THE COLLEGES—OBSTRUCTION AT THE COLLEGE OF SURGEONS—THE RECENT DISAGREEMENT AT THE COLLEGE OF PHYSICIANS.

LONDON, July 19, 1884.

THE present aspect of medical affairs is far from reassuring. I am afraid, if your readers were to give an impartial opinion on what may be termed medical politics here, it would be very far from complimentary to the powers that be.

The Government Medical bill is very likely not to pass, and few tears will be shed over it should it fail. There is scarcely any chance of its passing except in an emasculated and mutilated condition, and I believe the general opinion of the profession is that sooner than pass such a bill we had better go on as before. It is feared that the Government will accept Sir Lyon Playfair's amendment, which virtually neutralizes any good the measure may effect, by allowing the twenty licensing bodies to go on as before. Many people imagine this gentleman to be a medical man, as he was formerly termed Dr. Playfair. The doctorate was a German Ph.D., and its owner has no claim to represent the profession, although at the last general election Dr. Playfair so adroitly used his title as to make many of his constituents think he was really a medical man.

What are the colleges about? Nothing creditable. At the Surgical College the obstructives continue in power. They form a nice little family party, and when examinerships fall vacant elect one another to them, and draw nice salaries. The Senior Vice-President, Mr. Savory, has received £9,000 as fees for acting as examiner for a long series of years—about twenty, I think. He is one of the most unpopular examiners the college ever had, and is reputed—justly or unjustly—to delight in plucking. He is not ungentlemanly; he often smiles blandly on his victims, and the worse their ignorance the more pleased Mr. Savory seems. The only faint hope of reform lies in the fact that the Council have carried Mr. Heath's motion to "consider the mode of electing the president, and any alterations suggested in the method of proceeding in the election" in November next. Meanwhile, to break the old vicious rule of going by seniority, Mr. Holmes, the Junior Vice-President, declares that when it comes to his turn he will decline the presidency. We hope Mr. Holmes will have the courage of his convictions. If he has, he will acquire more repute as a reformer than he has ever done either as a teacher or an examiner.

Meanwhile the sister college has been rioting with closed doors. The proceedings of the Fellows have been declared to be *secreta collegii*, so they do not appear in the medical journals. What really occurred is no secret, although the most important part of the affair has not as yet been discussed in print. Some weeks ago, at a meeting of Fellows, the usual list prepared by the Council of proposed new Fellows was submitted to the Fellows present, and—unheard-of insolence—rejected by them. Why? The real grievance is that, of those proposed by the Council, almost all of them are not practising purely as physicians at all, although, of course, they all possess the M.R.C.P. The objectors, in fact, described them as general practitioners. Another wound was the fact that the list did not comprise a single University man. I must explain that by a "University man" the older members of the profession mean a graduate of Oxford or Cambridge. In times past these alone were eligible for the Fellowship. Sir William Jenner is an M.D. Lond., and not a blind worshipper of tradition. On the present occasion, so far from denying what

in fact could not be denied, he got up and defended it. He said the college had tried to get the general practitioners to join it and take the L.R.C.P., which was instituted for them, and, in short, why shouldn't general practitioners be made Fellows? This was virtually the gist of his argument, but the Fellows did not see as he saw, and after a stormy discussion refused the list bodily. Thereupon the Council took a month to consider before making out another list, and have even taken counsel's opinion. However, the real subject of offence has been declared to be a college secret, so none of the journals give any account of it, but merely give a meagre outline of what took place.

Meanwhile, those who have been offered the Fellowship by the Council and refused it by the Fellows are in a nice position. It is now customary for those who are proposed by the Council to be officially asked whether they will accept the proffered dignity (and pay their fifty guineas) before bringing their names publicly before the Fellows. Many years back, two gentlemen who had been duly elected Fellows in the general meeting of Fellows refused point-blank to accept the Fellowship. To avoid future indignities of this kind the Council adopted the present plan. Now where are they?

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 27 to August 2, 1884.

HEAD, JOHN F., Colonel and Surgeon. Ordered to Portsmouth, N. H., to meet the Greely party, and consult upon the proper course of treatment, with a view to the entire restoration to health of Lieutenant Greely and the men of his command. S. O. 177, par. 14, A. G. O., July 30, 1884.

WRIGHT, JOSEPH P., Major and Surgeon. Sick leave of absence extended three months on surgeon's certificate of disability. S. O. 176, par. 12, A. G. O., July 29, 1884.

WOODWARD, JOSEPH J., Major and Surgeon. Sick leave of absence extended six months. S. O. 178, par. 9, A. G. O., July 31, 1884.

MCELDERRY, HENRY, Captain and Assistant Surgeon. So much of S. O. 165, par. 12, A. G. O., July 16, 1884, as assigned him to duty in Department of the East, is revoked, and he is ordered to report in person to the Surgeon-General of the Army for duty in connection with the World's Industrial and Cotton Centennial Exposition at New Orleans, La. S. O. 173, par. 12, A. G. O., July 25, 1884.

FINLEY, J. A., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for one month extension, to take effect about September 1, 1884. S. O. 91, par. 2, Headquarters Department of Texas, July 22, 1884.

TAYLOR, A. W., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Riley, Kan. S. O. 153, par. 1, Headquarters Department of the Missouri, July 29, 1884.

GANDY, C. M., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to commence between August 15th and 30th, provided he furnish medical attendance at Fort Brady, Mich., during his absence. S. O. 144, par. 4, Headquarters Department of the East, July 30, 1884.

A MAN DURING A LIFETIME OF FIFTY YEARS, according to a paper recently read before the Academy of Sciences, Paris, sleeps away an aggregate of six thousand days, works away the same period, eats away two thousand days, walks away eight hundred days, is ill during five hundred days, and amuses himself with the remainder of his half century on earth.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 2, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
July 26, 1884	0	22	49	5	150	36	0	0
August 2, 1884	1	24	35	3	94	22	0	0
Deaths.								
July 26, 1884	0	10	10	5	31	18	0	0
August 2, 1884	1	6	7	3	19	14	0	0

PREVENTION OF ATTACKS OF CHOLERA.—Surgeon-General Cornish says: "It is within the experience of all, that an attack of cholera in the individual is often aborted by timely treatment. During an epidemic, what can be commoner than the following typical case? A man is suddenly seized with a feeling of oppression and sinking about the epigastrium, followed by two or three frequent and copious watery evacuations, and, if there be no actual sickness, a feeling of nausea and faintness. Such attacks often occur in the early morning, the patient having gone to bed perfectly well, and slept soundly until the desire to relieve the bowels was felt. Besides these symptoms, there is generally a clammy skin, a weak pulse, and much nervous anxiety. Now, let a case of this nature be treated instantly, by some combination of opium with a diffusible stimulant (a full dose of chlorodyne and brandy is perhaps the best and simplest remedy to be found at hand), let him be put to bed, and have warmth applied to his feet and epigastrium, so as to favor sleep. In nine cases out of ten, when the patient falls asleep, the diarrhœa is checked; and when he awakes, he will feel quite easy and comfortable. In the tenth case, the remedy may fail and the disease progress until all the symptoms of aggravated cholera appear in their due order. What becomes of the *contagium* of cholera, supposing the disease be due to an infective germ, when the early diarrhœa is checked?"—*Indian Medical Gazette.*

THE ETHICS OF THE SKIN.—Mr. Malcolm Morris, one of the ablest and most versatile of our brilliant younger school of dermatologists, has, says the *British Medical Journal*, made a decided hit by his sparkling and amusing, but very sensible and useful lecture, under this head, at the International Health Exhibition. The lecture was a pungent criticism of some of the morbid aspects of modern æstheticism. First, it was shown physiologically how much of a man's individuality lies in the skin. Remove an arm or a leg, or both arms and legs, there is yet left an individual man. But take away the skin, as the author of "Sartor Resartus" took away the raiment, and individuality is gone. The color of the complexion is due to the pigment-follicles, the red color of the cheeks to the terminals of the blood-vessels, seen through the transparent skin. The color of the skin is a test of health. But, within the last few years, we have experienced a remarkable artistic movement. The effects have been evident in the picture-galleries, they have displayed themselves in domestic life. Lastly, there has sprung up a taste that can only be postulated as a taste for disease, decrepitude, and decay. In one school, we find a bevy of woebegone women, ill, limp, and unwholesome. The men are not more attractive in a sanitary sense. They look like convalescents, ill-fed, and out of condition. This school is not very wide in its range, but

its influence is felt beyond the limits of its own lines. In the paintings of the older masters are ruddy Madonnas, clear-skinned goddesses, and chubby angels. In the more recent pictures, an etherealized skin is unduly popular. Of course, this repudiation of warm tints suited unhealthy people. Fashions change; and a time may come when it will be fashionable to be healthy, when normal hair will be popular, and natural skin the rage. When this sanitary millennium is reached, it is possible that the world will recognize that it is not attractive to daub the face with starch and rouge and bismuth, and paint after the manner of the heathen; that the bloom upon the peach cannot be beautified by whitewash; and that no chemical process can heighten the tinting of the heather-bell.

Corrosive Sublimate Solutions.—Sir Joseph Lister writes to the *British Medical Journal* that one drachm by weight of a solution of one part of corrosive sublimate in one part and a half of glycerine contains two-fifths its weight, or twenty-four grains of the sublimate. This, multiplied by 1,000 (the proportion of water required), gives 24,000 grains, which is very nearly three pints. It is, however, much more convenient to use fluid measure than weight, and a fluid drachm to the glycerine solution referred to requires four pints of water to produce the 1 to 1,000 solution.

The Micro-organism and Vaccine of Yellow Fever.—Prof. Domingo Freire, President of the Central Junta of Public Hygiene, Brazil, has sent to the *Sanitary News* an account of his experiments with the vaccine of yellow fever. We extract the following, calling attention to the unsatisfactory way in which he estimates the protective value of his attenuated virus: "The method of culture which I have followed is Pasteur's. I withdraw blood, or any other organic liquid, from persons sick with yellow fever, or from the bodies of the dead, using the most scrupulous precautions, and introduce these liquids into Pasteur's flasks, previously sterilized, and containing a solution of gelatine or beef 'bouillon.' In these conditions the microbe develops abundantly, and becomes of itself attenuated by the action of the air, which filters through the tampion of amianthus with which the flask is corked. The purity of these cultures is demonstrated by microscopic examinations, of which you will find a good illustration in my memoir 'Experimental Studies on the Contagion of Yellow Fever.' The microbe appears in the form of little black points, like grains of sand (780 diameters); in the mature form it presents the appearance of round cells with an ash-gray or black rim, containing in their interior yellow and black pigment and some granulations which will be the future spores. These cells burst at a given moment, and pour out their contents, *i.e.*, the spores, the pigments, and a nitrogenous substance composed of ptomaines, which I have isolated not only from vomited matter, but also from the blood itself, and from the urine. The yellow pigment, being very soluble, produces the icteric infiltration of all the tissues by a sort of tinctorial imbibition which may go on even after death; the black pigment, as well as the detritus resulting from the rupture of the cells, being insoluble, is carried into the general circulation and produces obstructions in the sanguine capillaries, whence the apoplectic symptoms so common in yellow fever, and in the urinary tubules, whence the suppression of the urine, a very frequent and terrible symptom in this disease. I have described this microscopic organism under the name of *Cryptococcus xanthogenicus;* its development resembling that of this genus of algæ. After having demonstrated the contagious nature of yellow fever by experiments upon barn-door fowls (see my memoir), I made experiments in preventive inoculations, first upon animals and afterward upon men. I did not fear to do this, because a multitude of experiments upon animals had previously convinced me of the perfect safety of inoculation with attenuated cultures. Up to this date I have vaccinated four hundred and fifty persons, for the most part foreigners recently arrived. Freedom from yellow fever has been pronounced among those thus vaccinated, for they have passed through a quite severe epidemic, and only six deaths have occurred among the four hundred and fifty vaccinated persons, that is to say, less than two in a hundred, while more than a thousand deaths have occurred among the non-vaccinated; the mortality of the non-vaccinated sick being about thirty to forty per hundred. Thus, if we take one hundred vaccinated persons, under the most favorable conditions as regards receptivity, we have only two deaths during the entire epidemic; if we take one hundred non-vaccinated sick, we have thirty to forty decedents, which gives a mortality fifteen times greater among the non-vaccinated. Even if the mortality were only ten times or five times less great among the vaccinated, the preventive measure would be worthy of adoption. The protective inoculation for charbon gives an immunity to one-tenth, and that of vaccination for small-pox guarantees an immunity to one-fifth, according to the calculations of Bousquet."

Where Hip Diseases are Treated.—Dr. N. M. Shaffer, of this city, writes: "Will you please permit me to correct a misstatement which occurs in your issue of May 31st, in your review of Dr. Gibney's work on 'The Hip and its Diseases?' The reviewer alludes to the Hospital for the Relief of the Ruptured and Crippled, of which he says, 'where more cases of hip disease are annually treated than in any other similar institution in the country.' A few brief extracts from the annual reports of the Hospital for the Relief of the Ruptured and Crippled and those of the New York Orthopædic Dispensary and Hospital will prove the incorrectness of your reviewer's statement. Cases of hip disease annually treated by the Hospital for the Ruptured and Crippled: For the year ending April 30, 1879, 167; for the year ending April 30, 1880, 160; for the year ending April 30, 1881, 170; for the seventeen months ending September 30, 1882, 251; for the year ending September 30, 1883, 173. Total for five years and five months, 921. Cases of hip disease annually treated by the New York Orthopædic Dispensary and Hospital: For the twenty-one months ending September 30, 1880, 401; for the year ending September 30, 1881, 328; for the year ending September 30, 1882, 376; for the year ending September 30, 1883, 420. Total for five years and nine months, 1,525."

Benzoin promotes bronchial and cutaneous exhalation; a large part of the acid is excreted by the kidneys as benzoic acid, and a part is changed into hippuric acid, so that it renders the urine decidedly acid. It and the benzoate of ammonia are very useful when the urine is very alkaline or ammoniacal, and loaded with phosphates. It renders the urine acid, and arrests ammoniacal and fermentative changes in the bladder. Phosphatic calculi are said to be dissolved by the long-continued use of it. Foul smelling, unhealthy, and sloughing wounds, and flabby granulations are improved by the ointment or tincture. It destroys fetor and stimulates to a more healthy growth. It has some antiseptic powers, and prevents fermentation and putrefaction, and is as useful in ulceration of the bowels as it is in open superficial ulcers. It may be given in pill form.

Errata in Dr. John N. Mackenzie's Article on Coryza Vasomotoria Periodica, in The Medical Record of July 19th.—Page 59, first column, 25th line from commencement of article, for "mere" read "more;" second column, 18th line from top of page, for "intelligent" read "intelligible;" 25th line from top of page, for "Daley" read "Daly." The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 26, No. 7 NEW YORK, AUGUST 16, 1884 Whole No. 719

Original Articles.

THE CAUSES OF DISEASE,

AS VIEWED FROM THE STANDPOINTS OF PREDISPOSITION, HEREDITARY INFLUENCES, RACIAL PROCLIVITIES, EPIDEMIC CONSTITUTION, AND VITAL RESISTANCE.

Being the Substance of the Presidential Address delivered July 29, 1884, before the Fifty-second Annual Meeting of the British Medical Association, held in Belfast, Ireland.

BY JAMES CUMING, M.D., F.K.Q.C.P.,

PRESIDENT-ELECT OF THE ASSOCIATION, AND PROFESSOR OF MEDICINE IN QUEEN'S COLLEGE, AND PHYSICIAN TO THE ROYAL HOSPITAL, BELFAST, IRELAND.

(Special for THE MEDICAL RECORD.)

THE principal interest in regard to the progress of medical science is at present concentrated on the study of minute organisms as causes of disease. The identification of the special parasites, the study of their mode of invading the body, of the places of their development, of their effects in respect of nutrition, function, and tissue-change, present subjects for investigation of surpassing interest and engage the attention of numerous observers. Evidence is rapidly accumulating which leaves little room to doubt that micro-organisms are the active agents in the production of epidemic and endemic diseases. A flood of light has been thrown on some of the obscurest points of pathology, the reproduction and increase of contagious elements, the immunity acquired by passing through a disease against a recurrence of the same malady, and on the question of the incubation and latency of contagious diseases. Nothing can be of greater interest than the observations on the attenuation of virus, opening out unexpected possibilities of mitigating the severity of some of these scourges of the human race, and making the hope of the ultimate extirpation of several of them not altogether a fantastic one. In the main we have to look to foreign observers for our instruction in these subjects, for in these countries the researches necessary to elucidate such problems are trammelled by legislative interference and markedly discouraged by popular sentiment. In recent years it had become one of the commonplaces of general addresses on medicine that disease was to be regarded as simply a perverted life-process, and that there was an essential identity between physiological and pathological processes. We used to congratulate ourselves on the strides we had made in advance from the notions of the earlier physicians who regarded disease as an intrusive foreign element at war with the vital principle. Boerhaave is credited with being the first to formulate the great principle, "Morbus est vita præter naturam." And undoubtedly this conception did lead to clearer notions of many of the phenomena of chronic disease. But what is the outcome of the most recent researches on bacterial action? It is, that when bacteria enter a tissue they come into conflict with the proper tissue-elements, abstract the nourishment contained in the juices to the detriment or exclusion of the normal cells, and give rise to different chemical changes which disturb the normal metabolism of the healthy parts. After all, in different language, the old idea was not so very wide of the mark as we supposed. If the vital activity of the parasite gets the upper hand, the life of the normal cells of the organism is enfeebled or destroyed, and *vice versa*. It is the old struggle between Ormuzd and Ahriman within the sphere of nutritive activity. Now investigations on these subjects, can only be conducted by those who have the leisure and aptitude for original research, and must accordingly be left in the hands of the few. But there is another vast field of inquiry which is not beset with the same difficulties, and which forms the necessary complement of the study of the parasite. We know that there must be a certain receptivity in the system, some diminution in its wonted powers of resistance, or some original proclivity—something which we are in the habit of terming predisposition—which renders the body liable to the attacks of the parasite and furnishes an appropriate soil for its growth. This predisposition may be either a general one expressed by a proclivity in some countries or in certain races, or in particular temperaments, or it may have been acquired by the individual either at a certain period of life, or under the influence of a variety of causes in his diet, occupation, or surroundings.

Now it is precisely with reference to these points that we can get most light—I had almost said the only light—from the general experience of the profession. A great deal of medical literature is founded on hospital practice, which, valuable as it is, wants the element of time. The floating population of hospitals passes rapidly from under observation, and it is only from the medical men who have known patients for years, and often the stock from which they come, that we can get information which necessarily presupposes continuous observation spread over long periods.

It is in respect to questions of this kind, which are so clearly within the scope of every practitioner of medicine, that I look for the best results from the labors of the Collective Investigation Committee, which I have no doubt will prove one of the most valuable of the agencies for good in this Association; and I am not without hope of a still larger and more ambitious effort, which will embrace not only this but all civilized countries in its operation, and that we may have an international collective investigation of disease. From such an organization we could obtain an immense amount of information on the subject of climatic and telluric influences, and on the question of racial proclivities to disease, as well as on the important subject of diathesis.

The subject of the proclivities of different races to disease is one of great interest, and has been but little investigated. The facilities which the vast colonial empire of England offers for observation to medical officers of the public services have enabled them to see much of disease in different countries of the world; and, no doubt, there is a good deal of information entombed in the army and navy reports, but we have but little definite knowledge. That the negro race enjoys a comparative immunity from yellow fever, and that even a slight admixture of negro blood brings with it a certain degree of protection from this malady, seems well ascertained. The comparative freedom of the same race from stone, and, on the other hand, their marked liability to elephantiasis and to tetanus are clearly made out. Again, there is reason to believe that different branches of the Aryan or Indo-European family present some peculiarities in respect of liability to morbific influence.

In France, where, from the requirements of military service, statistics with respect to some classes of affec-

tions are easily accessible, it has been found that in the provinces where there is most Teutonic blood there is a notably greater number of exemptions from service owing to varicose veins and hernia than those in which the inhabitants are of Celtic origin. On the other hand, it is considered by some that the Celtic people do not bear surgical operations so well. When Velpeau was reproached with the greater mortality after operation in Parisian, as compared with English hospitals, he is reported to have replied that the flesh of a Frenchman was not the flesh of an Englishman. And all who, in recent years have had the privilege of visiting the wards of M. Charcot in the Salpetrière, have been able to notice a variety of rare and complex diseases of the nervous system which are certainly but rarely to be met with in these countries, and which he has used in so able and instructive a way. Again, it is probable that drugs act differently on different races; the negro, for example, bearing mercury better than the white, and being somewhat differently affected by opium. There are also the analogous facts of the insusceptibility of some animals to poisons which act with fatal effect on others.

Without entering on the subject which was so hotly debated some time ago, whether a change of type in disease has taken place, there can be no doubt that a change of epidemic constitution, using the term in a wide significance, has taken place, and that the same diseases do not prevail with the same frequency. There can, I think, be no doubt that typhoid fever is much more common in Ireland than formerly, if indeed it existed at all, and that typhus is much less frequent.

Now the important subject of diathesis is closely allied to this class of inquiry, and is eminently adapted for collective investigation. It is a condition in which large numbers of individuals are implicated, and in which a large array of facts is of primary importance, and it is also one in which continuous and prolonged observation is eminently and especially necessary.

What may be the nature of the peculiarities of structure and of function which imprint a particular character on the morbid manifestations which an individual exhibits it may not be possible for us to ascertain with certainty, but there is no fact capable of more overwhelming clinical demonstration or which is of more cardinal importance in the management of disease. It is a state in which, under the influence of exciting causes, or perhaps without any exciting cause, morbid phenomena are manifested, diverse in their seat, their extent, and their character, but united by a common pathological bond, which is shown in their mode of evolution and recession, and in a kindred demeanor with respect to therapeutic influences. It is a constitutional state which exists before, and often long before any local manifestation whatever, which is, I have said, obscure as regards its nature, but distinctly recognizable in its effects, and which we know in several instances to arise from well-recognized causes. It enrolls the individual who is affected with it in a category apart from those who are not under its influence, and in this way approximates to a racial peculiarity, the analogy being all the closer that diathesis is in many instances capable of transmission to the descendants of those who are its subjects.

I dwell on this the more because I think it specially the province of the practical physician, and because it constitutes the most typical expression of a class of facts which are forced on us by daily experience. We all know that an affection of the nervous system or the digestive system represents a different thing, as regards the outlook and the present danger, in one family as compared to another. There are not wanting indications of a tendency which takes its direction from very high quarters to assign an undue predominance to anatomical change to the exclusion of constitutional states. The greatest living pathologist, Professor Virchow, of Berlin, in his address at the International Medical Congress in 1881 spoke as follows: "How has it now come to pass that symptomatology has entirely lost the high position in which it still stood little less than a generation ago, to such an extent that in most universities it is no more taught as a specialty? Have symptoms no more any importance for the physician? Can a diagnosis be made without a knowledge of symptoms? Certainly not. But for the scientific physician the symptoms are no more the expression of a hidden power, recognizable only in its outer workings; he searches for this power itself, and endeavors to find where it is seated in the hope of exploring even the nature of its seat. Hence the first question of the pathologist and of the biologist in general is, Where? That is the anatomical question. No matter whether we endeavor to ascertain the place of the disease or of life with the anatomical knife or only with the eye or the hand, whether we dissect or only observe, the method of investigation is always anatomical."

I do not think that this doctrine will find acceptance with practical physicians. We believe that many morbid phenomena are not to be looked for as merely the expression of local change, but as portions of the effect of some specific cause; that the disturbance of function, otherwise the symptom, often precedes the tissue alteration, and that we might be justified in stating the seeming paradox, that the symptom sometimes causes the lesion rather than that the lesion causes the symptom. Medicine teems with instances in which anatomical change alone would lead us very far from the result which clinical observation indisputably establishes, and there is no lesson which experience teaches a physician more decisively than that it is not the extent or degree of an inflammatory affection which furnishes the most accurate measure of its danger or the most reliable indication for its treatment. Indeed, in dealing with many cases of disease our question is not, Where is it? but, What is it? Is it gout or syphilis or malaria? and so on; as we are well assured that if we have got the key to the enigma all the varied anatomical changes will become explicable, and, what is of far greater moment, will be found amenable to remedies. We have often occasion to observe that anatomical changes, not to be easily differentiated, follow from life processes which are very dissimilar. That symptoms without morbid anatomy are inadequate and misleading for the purposes of the physician, has been only too amply demonstrated in the records of medicine; but it is no less certain that morbid anatomy without symptoms—that is, without giving a due and even a preponderating weight to the origin and progress and vital character of the disease—will lead to error hardly less disastrous.

It had been one of the characteristics of Irish medicine that this conception of the essentially vital character of morbid manifestations has been firmly grasped and strongly insisted on. In the latest work of Dr. Stokes—a name always to be mentioned with honor as one who was an honor alike to his profession and to his country, and who has special interest for this Association, of which he was President at the Dublin meeting—he says:

"So far as medical experience goes, we are forced to admit that the foundations for the healing art must rest on another, if not a broader basis than that of anatomical and of chemical changes in disease. There are differences—and for want of a better name we may call them vital—which more intimately relate to life and health than to the anatomical or chemical changes produced by disease; and these are to be reached by the study of the living phenomena of the body and of the influence of agents upon them. In truth, the fruitless attempt to base medicine upon anatomical or even chemical changes should be a lesson to those who neglect the infinitely varied mutations of vital or of nervous action."

It is not that this great physician did not recognize in the fullest manner the necessity for the closest physical examination during life and the most careful scrutiny of morbid products: much of the labor of his life, as is well

known to us all, was devoted to the elaboration and perfection of that physical diagnosis of which he was so consummate a master; but that he refused to recognize the results of disease as adequate to the interpretation of morbid processes.

It is impossible not to believe that if clinical evidence had not been allowed to be overborne by pathological theory, there would have been much less difficulty and much less confusion about the relationship between pulmonary consumption and struma or scrofula. We may select this as an illustration, because scrofula is an affection with which we are very familiar in this country, although probably it is not more general here than in England and Scotland. On broad public grounds there are few conditions of greater moment than scrofula as influencing the well-being and development of the youth of the community. Defacing the comely skin and clouding the clear eye of childhood, disfiguring and scarring the neck and crippling the supple limbs, it is undoubtedly one of the most wide-spread and unsightly forms of human infirmity. Complex in its causation, and favored by all the concomitants of poverty, insufficient diet, scanty clothing, want of light and air and sunshine, it is no doubt in many instances connected with the use of a dietary deficient in animal and vegetable fats, a view strongly advocated by the late Professor Hughes Bennett, and which has received the support of an authority no less eminent than Mr. Jonathan Hutchinson.

Now I cannot but believe that if the facts of the clinical history of scrofulous affections had not been overborne by pathological considerations, there would be much less difficulty in ascertaining the relations between scrofula and pulmonary consumption. The reports of the Collective Investigation Committee have shown a preponderating testimony in favor of the view toward which the current of medical, as well as popular, opinion has been setting—the communicability of pulmonary consumption. Now after a period during which consumption seemed in a fair way of being considered to depend on anything but tubercle, we have come to the conviction that, broadly speaking, tubercle is the anatomical element of the malady. There is no doubt that a pathological product, not to be distinguished from tubercle, is met with in some scrofulous glands, and from this circumstance, if we dealt with disease simply as pathological anatomists, and not as physicians and surgeons, we should pronounce an opinion very favorable to the identity of the two affections, and state that an individual with a scrofulous gland and another with pulmonary consumption were alike the victims of tubercular disease, and although we would in doing this group together affections widely different as regards their gravity and prognosis, we would be acting on strict pathological lines. But when we examine another numerous class of strumous cases, those in which the eye and skin are affected in childhood, we find no evidence of tubercle whatever; indeed, in the progress and issue of the affections, decisive evidence that tubercle is not present at all, and accordingly we are able to convince ourselves, not only from this circumstance, but from the examination of many more advanced forms of these affections, that tubercle is not a necessary accompaniment of struma. Now, so much have the minds of pathologists been influenced by the occasional presence of tubercle in struma, that it has been broadly stated that consumption is a further stage of scrofula and that the two affections are identical, except in so far that scrofula represents an external and rudimentary form of the disease of which pulmonary phthisis is the more advanced and complete manifestation. At this point clinical observation has a right to enter and deliver a formal protest. Dealing simply with the facts which come under our notice we find in scrofula a condition most common in the young, although by no means exclusively confined to them; revealing itself by a variety of manifestations very chronic in their character, liable to be set up by trivial exciting causes, and remarkably prone to affect lymphatic structures. These phenomena are in the main capable of easy recognition, and form a clinical type which is evidently a natural one. They are evidences of a diathesis which makes those under its influence a class different from others in the vital endowments of their tissue. Of those who exhibit this diathesis in childhood, a considerable proportion grow up into fairly healthy men and women, capable of performing the duties of active life, and giving no palpable indications of disease. But they still show a certain vulnerability of tissue, and proneness to some chronic affections of the same kind, in fact a particular "cachet" which explains the anomalies in their vital reaction. Nothing can be a more legitimate and incontrovertible inference from the facts than that an individual may have been distinctly and markedly scrofulous, and yet never exhibit any indications of consumption.

On the other hand, of the consumptive patients who present themselves to a physician for advice about their lungs, a large proportion, estimated at about eighty or ninety in the hundred, have never had a history of scrofulous affections in childhood, and show no present evidence of the taint. It is quite exceptional to find a phthisical sufferer showing such indications. Clearly, then, an individual may become phthisical without being scrofulous, and considering the wide diffusion of struma and the great frequency of pulmonary consumption this seems decisive. In a recent able work on scrofula Mr. Treves has laid down the proposition, as the result of the observation of a great number of cases, that there is a decided antagonism between scrofulous diseases of all kinds, and that if a patient has one severe, or even well-marked manifestation of scrofula, he is not likely to develop another strumous disease at the same time. Contrast with this the well-known law of Louis, that the presence of tubercle in any organ after the age of fifteen involves as a necessity its existence in the lung, and we see how contradictory these assertions are if we depend altogether on the character of the product. The product known as tubercle has, after the age of fifteen, the property when present of causing the development of a similar morbid product in the other parts. Therefore, the tubercle found in scrofula in childhood has not the same relations to the system as the tubercle found after fifteen years of age. It is, of course, unnecessary to say that a lymphatic gland furnishes one of the easiest and most direct channels for the conveyance of infection into the system. Now this is not a mere question of terminology, for the attempt to unite different states on the basis of a common anatomical character invariably associates them in the mind as identical in all essential respects and is very misleading.

We ought to deal with the recent observations which point to the bacillus tuberculosis in the same spirit. When we are informed by Koch that he has found the same parasite in caseous bronchitis, caseous pneumonia, phthisical sputa, and in the hyperplasia of lymphatic glands, a clinical observer is justified in listening to these statements with the greatest interest, but with considerable reserve. He has a right to inquire how is it that an infective granuloma does not infect, and how is it that an enlarged lymphatic seems to demean itself in very much the same way, whether it is the seat of a simple chronic inflammatory process or of a new formation containing an intrusive organism profoundly dangerous to the economy and tending to invade one part of the system after another.

In fact, while we ought to welcome every new method of investigation, while we ought to do nothing to discourage the boldest flights of pathological speculation, to us the crucial test must always be the clinical one, the facts drawn from the direct observation of morbid processes during life. And in spite of any pathological generalization or anatomical induction we must hold rigidly to our clinical facts and decline to allow them to be warped or strained in the slightest degree.

Looking at the matter from the point of view of a practical physician, how different is the outlook as regards a young person brought to us with a strumous ophthalmia and enlarged glands in the neck and one of the same age with a little dulness and a few moist sounds in the apex of a lung. Is this wide difference in prognosis a question merely of a difference in seat of an identical pathological product? Is there not, as a rule, some antecedent condition which favors, if it does not determine, the appearance of the morbid state? Is it not a rare thing to find a phthisis beginning without, for example, a period of loss of appetite or indifferent health of some kind? Do I then wish to say that there is no connection between scrofula and consumption? I should not wish to be understood as making this statement.

There exists a certain kinship which makes the two conditions sometimes overlap, and there is some evidence that a hereditary tendency may sometimes be expressed in the one form and occasionally in the other.

It is proposed to inaugurate at this meeting a section devoted to pharmacology and therapeutics. The subjects embraced in this section have hitherto been scattered through different departments, but the increasing importance of their study justifies their being assigned to an independent section. The study of the action of drugs on the body both in health and in disease, and the study of all the means by which a disease may be mitigated or cured, form a necessary complement to the study of the disease itself, and even throw as much light on its nature.

In recent years the efforts in the direction of establishing rational therapeutics have been followed by great and encouraging success, while the search after specifics has disastrously failed. The study of antipyretics presents, in a striking light, the results of inquiry conducted in a strictly scientific method and spirit, and I am glad to find that one of the earliest discussions in the new section is to be devoted to this most valuable class of agents. New remedies of unquestionable power are being placed in our hands. It is impossible to read the account of the employment of kairin without being struck by its great efficacy in reducing temperature.

In recent therapeutics we find also an illustration of what I have before endeavored to show. In treating acute disease, it is, as a rule, the functional trouble that engages our attention and constitutes the aim of our therapeutic measures. Heat, delirium, circulatory or nutritive disturbance, adynamic symptoms—these are the conditions to which we direct our remedies. How comparatively rarely do we attack the tissue-change directly, and how comparatively inoperative are our therapeutic agents in this direction. It is true, of late years and since the investigations of Pasteur, that wider and more attractive possibilities have come into view, and the hope is entertained that agents may be placed in our hands which, without injuring the body, may prove incompatible with the life and development of some, at least, of the parasite organisms. That a particular salt promotes the growth of an organism, that another in even exceedingly minute quantity is fatal to it, gives some ground for the notion that it may be practicable to destroy some of these formidable enemies even within the body. Again, the methods of therapeutic research have been much improved.

The employment of the alkaloids or active principles of drugs in conducting experiments on their nature, instead of tinctures and powders of necessarily uncertain strength, has enabled a degree of accuracy to be obtained in estimating the effects produced which was formerly quite unattainable, and give additional scientific precision to the conclusions which are attained. For my own part, I regard every advance in therapeutics with great interest. The true dignity as well as the chief attraction in our studies lies in their practical utility. If our efforts were not quickened by something more than love of knowledge or scientific curiosity, the study of disease would be at best but a repulsive one.

"Res ipsa ornari negat contenta doceri."

No doubt there is an intellectual gratification of a high kind in contemplating a well-ordered field of knowledge where the divisions are clearly mapped out, and their relations, extent, and connections can be accurately understood. And it is also true that the study of medicine exercises a powerful and beneficial influence on the development and cultivation of the intellectual faculties.

It was said by Dugald Stewart that the study of medicine had an important influence on the development of one of the keenest intellects of modern times.

"No science could have been chosen more happily," he says, "to prepare such a mind as that of Locke for the prosecution of those speculations which have immortalized his name, the complicated and often equivocal phenomena of disease requiring in the observer a far greater portion of discriminating sagacity than those of physics properly so called; resembling in this respect much more nearly the phenomena about which metaphysics, ethics, and politics are concerned."

It is not possible that medicine should be cultivated on exactly the same lines as other sciences. In the first place, we are necessarily precluded from experiment; in the next place, we have but limited control over the subjects of our art. It was long ago pointed out by Bichat that pathology, the science of disease, has no exact analogue among the physical sciences. Physiology bears the same relation to living bodies that mechanics and the like do to inert matter. But there is no pathology of the physical sciences. We cannot suppose gravity to become deranged in its operations or chemical affinity as subject to morbid action. Nor can we suppose these forces are susceptible of remedies. Accordingly the processes of disease must be made the subject of investigations of a special character; to be conducted, certainly, according to the general principles which govern all scientific research, but not on the same lines or by the same method which other branches of inquiry demand. The study of life and its manifestations, of its beginnings and its endings, conveys the idea of effort, sometimes baffled, sometimes victorious, of an incessant struggle with its environment compared with which the physical forces seem types of serenity and calm.

Bacon advised physicians to raise their thoughts above common cases, and to turn them to prolonging and renewing the life of man. But, like much of the advice which men of great intellectual attainments have given to our profession, it only served to show that he had failed to recognize the essential conditions of our art. It is given to philosophers to generalize: to us the individual is everything. Aristotle and Seneca advised that, for the good of the race, delicate children should not be brought up. It is our duty to fan the puniest flicker of vitality and to preserve it from extinction as long as and as far as the most jealous care and solicitude can be effectual for the purpose. What the sick or suffering ask of us is, to have their pains and maladies mitigated or cured in the speediest and most effectual way. "Melius anceps remedium quam nullum" is a maxim which may not be a very wise one, but which certainly would fairly represent the desire of the great majority of the human race. There is deep truth in the saying of Bacon: "They be the least physicians which being learned incline to the traditions of experience, or being empirics incline to the method of learning," for it indicates that the physician should draw from all sources of knowledge alike. It used to be a reproach to physicians that they followed too implicitly the teaching of their masters and that they were unduly slow to accept new ideas; at the present day we are no longer liable to this reproach. One is almost inclined to suggest that even an undue haste is occasionally shown in adopting suggestions which rest on insufficient evidence or obser-

vation. It shows, however, a change in the habits and temper of mind which is in close accordance with the general spirit of the age. It is well that novel views should meet, as they are sure to do at our meetings, that rigorous and searching criticism which is the surest test of truth and which best proves its strength and vitality. It is one of the numerous advantages of a great association like this that different men may seek different services from its strength and organization. One regards especially its usefulness in bringing the weight and influence of a great profession to bear on public questions; another may value it for its beneficial influence on the status and relations of the members of the profession themselves; while others again attach more importance to its strictly scientific aspect, and desire that its resources and energy should be devoted to the encouragement of research, the fostering of investigation, and the general furthering of medical science. In the elasticity of its constitution, in the adaptability of its machinery, and in the independence of its branches, there is ample scope and abundant facility for the utilization of the varied energies of its members. In this respect it is no unfitting representative and exponent of the great profession out of which it springs. Called as we are to deal with the evils and mischances to which every form and variety of human activity are exposed, our points of contact with the public are well-nigh innumerable.

"Quidquid agunt homines," the worn-out limb, the jaded sense, the weary brain alike come under our ken. Every avenue of pleasure may become the portal for the ingress of pain. And so our studies embrace a vast and complicated range of subject, and give to medical science a wide and far-reaching scope of activity. And as it is now, so it has been and will be. When hygiene and preventive medicine have done their utmost, there will still be only too ample scope for the physician in dealing with the innumerable forms of human infirmity. The foundations of our art have been laid in antiquity beyond the reach of historical research; in this progress it has reflected innumerable aspects of human thought; its terms are the monuments of forgotten theories; to its storehouses of knowledge all civilized nations have brought their contributions.

It will be found that if in its course of development medicine has shared the errors and shortcomings inseparable from human progress, its advances have been in the main fairly abreast of those made in other branches of knowledge.

It is for us to maintain in our day the dignity and usefulness of a profession which has included in it so many good and famous men, and which has been for so many centuries among the foremost branches of intellectual activity.

Refusing to be Vaccinated.—There are persons here and there to be found who refuse to be vaccinated, and some of them give the ground of their refusal to be "principle." A person of this character appeared in an English court not long ago to answer the charge of refusing to allow his three-year-old child to be vaccinated. The magistrate fined him, although his action was stated to be "on principle." As the fine was not paid and could not be collected, the offender was sentenced to Portsmouth prison for fourteen days, but without hard labor. While in jail he was obliged to wear the criminal's garb, had to sleep on a plank bed, and was compelled to pick oakum. He wished to secure his own food, offering to pay for it, but the authorities declined to let him have anything except the ordinary prison fare. These facts were brought before the judge by his counsel, who contended that he was not an ordinary prisoner and should not be subjected to such treatment; but the court decided that the law had been broken, and that the offender could not claim any better treatment than any other prisoner.

PRACTICAL OBSERVATIONS ON THE HUMAN EAR AND ITS DISEASES, WITH ILLUSTRATIVE CASES.

By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I.—The External Ear.

(Continued from No. 718, p. 153.)

Sometimes it happens that the regressive stage runs on into a chronic condition, and the walls of the cyst fail to unite, or else a permanent sinus remains. Under these circumstances it will be necessary to *destroy the secreting surface of the cyst.* This may be accomplished either by the application of escharotics or irritants to the walls of the cyst, or by scraping them with the cutting instrument shown in Fig. 2. In regard to the selection of an irritant for this purpose, I have found none equal to a strong solution of iodine. The operation consists in making a tolerably free incision into the tumor, or in enlarging the sinus where one of small size exists, cleansing out the cavity, and then freely painting its surface with Churchill's solution of iodine. The walls of the tumor are afterward to be kept in contact by pressure. In my own experience, the injection of small quantities of the tincture of iodine into these tumors has proven to be temporizing and unsuccessful. Case II. is an example of the advantages of the method recommended above. When the operation already described fails, or for any reason seems inadvisable, the surface of the walls of the tumor may be abraded throughout with the fenestrated cutting scraper. This method, which was the suggestion of Dr. G. H. Fox, is preferable to escharotics, since the disorganization of tissue is entirely within the operator's control. This treatment was employed in Case III. Where any projecting edges or sharp folds of the cartilage prevent the walls coming together, they may, where the correcting of deformity is desired, be *extirpated by dissection.* This can readily be done by making a sufficient incision down into the outer surface of the auricle, and with knife and scissors removing the inequalities of the distorted cartilage. If thought advisable, the surfaces of the cavity may be afterward treated by painting with iodine or scraped. After the operation the walls should be kept in contact by bandaging (pressure). In the writer's experience, otoplastic operations can be performed with considerable freedom in these cases without fear of undue reactive inflammation, the wounds healing readily in the insane, even where low recuperative action might be expected to exist.

The occurrence of othæmatoma in the mentally sane is uncommon; a glance at the literature of the subject shows that it has been comparatively seldom the subject of observation among foreign writers, while American authors have thus far reported only some ten cases.[1] The writer ventures to introduce here a few illustrative cases occurring in his own practice, believing that an account of their behavior and management may be of interest in this connection, none of them having been hitherto reported.

Case XI.—A gentleman, forty-three years of age, a lawyer by profession, who had always been healthy, came to consult me on November 22, 1876, with the following history: On November 12, 1876, he discovered the presence of a small tumor on the upper and outer aspect of the left auricle. It gave him so little trouble that he did not consult his physician, Dr. W. C. West, of Monroe, Mich., until a week afterward. Dr. West then removed the small collection of serum which the tumor contained by aspiration. The effusion now increased

[1] Vide C. J. Blake: Statistical Rept. of 1,632 Cases of Diseases of the Ear, treated at the Mass. Ch. Eye and Ear Inf. during the year 1872; one case of othæmatoma—A. J. Otol., vol. iii., pp. 191-196. H. Knapp: Arch. Otol., vol. ix., pp. 195-202. Roosa: Trans. Am. Otol. Soc., vol. i., pp. 23-127. Kipp: Trans. A. O. Soc., vol. i., p. 79. Pomeroy: Ibid., vol. ii., pp. 83-86. Buck: Diagnosis and Treat. of Ear Diseases. Pooley: Medical Record, vol. xix., pp. 313-315.

more rapidly than before, and on the 21st of November the operation was repeated, the liquid withdrawn now being sero-sanguinolent. Urgent business at this time requiring the patient's presence in New York, he came to my office as stated above. The tumor was now found to be about the size of an olive, but thinner, and to have a purplish color. The distention was causing some discomfort, and half a drachm of bloody serum was evacuated by aspiration, after which the organ did not appear much larger than normal. The patient remained six days in New York, during which time there was but little change in his condition; the cyst was evacuated daily, and twice a few drops of tincture of iodine were injected, which increased the irritation somewhat —the auricle becoming slightly more swollen and tender to the touch, but receding again to its former state. While in New York the patient's business required much activity both of a physical and mental nature. Before leaving for home he recalled having *folded up the auricle upon itself by an accidental blow with his own hand while playing with one of his children a short time before he discovered the cyst.*

The patient left for his home on November 28th. He took a severe cold during the journey, and Dr. West found him, on his arrival the next day, suffering very much from the distention of the cyst, the contents of which were evacuated as before. On the 29th he was restless, the temperature going above 100°. A purgative and aconite were ordered, together with cooling lotions and gentle pressure. The latter, however, could not be borne. On the 30th the patient felt better, but the local trouble was extending, and now a colored spot was discovered on the back of the auricle. Iodine was injected into the cyst.

From this time on the patient continued to grow worse; the eyes became sensitive to light, and there were darting pains through the head. The inflammation extended itself to the parts above the ear; there was now effusion both in front of and back of the cartilage. Sedative doses of aconite were continued, and a laxative and quinine were given; an incision fully an inch in length was made, which laid the anterior aspect of the cyst freely open. The wound was then packed with lint soaked in carbolized oil. "The operation afforded immediate relief," says Dr. West, in his report of the case to me, "and in a few days there was an improvement in the symptoms." Tonics were then given. The patient was confined to his bed, however, during the month of December, and for the period of another month to the house. In May, 1877, the auricle was yet quite tender to the touch, and sensitive to draughts of air, although the parts had been for some time entirely healed. When the patient came to see me, in February, 1880, it was found that the auricle was considerably deformed, the superior portion of the cartilage being much contracted, the antihelix quite obliterated. In reviewing the case, it was evident that the long railway journey, the want of proper rest, and, above all, the cold contracted, made a severe case out of what would have been, perhaps, a mild one.

Case XII.—R. B——, a packer, forty years of age, came to the New York Eye and Ear Infirmary, August 2, 1877, with a small sanguineous tumor on the outer aspect of the left auricle, between the helix and antihelix, near the superior border. The tumor was of a deep red color, and slightly painful when handled. No urgent symptoms were present, and no subsequent visit was made.

Case XIII.—Ellen M——, a tailoress, aged twenty-seven, but looks much older. Came to the New York Eye and Ear Infirmary November 29, 1880. She is very intemperate, and the teeth are nearly eroded away by caries until they are about on a level with the gums. She states that one month ago the left ear was violently jerked by her husband, and that the next morning it swelled up and was of a very dark purple color. A day or two afterward the husband opened the swollen tissues with a blade of his pocket-knife. This operation increased the swelling, and a few days afterward a "doctor" laid the outer aspect of the tumor open with a lance. The cyst now became intensely swollen, and was as large as the patient's "fist." The husband then came home again in a drunken state and struck her on the

Fig. 7.

ear, causing a discharge of its contents to take place from the superior surface of the auricle. Flax-seed poultices were constantly applied to the ear during the attack. The posterior surface and the lobule were at no time affected. From the first the ear was for a while painful. For the past two weeks the swelling has diminished, but since yesterday it has again increased in size, the patient says "from the effects of taking cold in the ear." The tumor is now hard, and in size about one inch in thickness, and from above downward one and three-fourths of an inch in length. It is oval in shape; its outer surface is corrugated and somewhat resembles an almond that has been divested of its outer cortex. It is not sensitive to the touch, and in color is dark red, like the rest of the face and neck. Hearing is unaffected. The ears are naturally small. Fig. 7 shows the affected ear's appearance at the time of her first visit. The local treatment was expectant; internally the tincture of aconite root was ordered in small and frequently repeated doses. Rest and better personal hygiene recommended.

December 6th.—She comes to-day with a painful alveolar abscess at the root of the left upper central incisor tooth. Sent to the dentist to have tooth removed.

December 9th.—The left side of the face is much swollen from the presence of the alveolar abscess, which, however, is no longer painful. The ear is also without pain. Were it not for the unsightliness of the abscess and the painful mastication, the patient would not have returned to-day for treatment. She was not again seen.

Case XIV.—Mr. S——, a dry goods merchant, aged twenty-five, came to consult me on October 17, 1881. Two months previously he had received an injury to

the right ear by being jammed against a door while in a state of intoxication. Twelve hours afterward he experienced soreness of the auricle, which was limited to the upper part of the helix; this continued without observable swelling for six weeks. Two weeks ago he noticed that the outer aspect of the ear was "puffed out," and two days later an incision was made into it by a physician to whom he went at the time; there was an escape of sero-sanguinolent fluid, but by the next morning the incision had closed and the cyst had refilled. Two days later another physician was seen, who cut the parts open with scissors, and on the following day increased the size of the opening by making a crucial incision. It seems that these measures were not sufficient to prevent the filling and distention of the sac, and that five days before coming to me a "piece was cut out," and the cavity then packed with oakum. Subsequently efforts were made to bandage the ear to the head. The oakum was allowed to remain for three days, and the ear was then poulticed. When I first saw the case the auricle was very much enlarged, had an angry look, and was of a purplish color. (See Fig. 8.) It was not very tender to

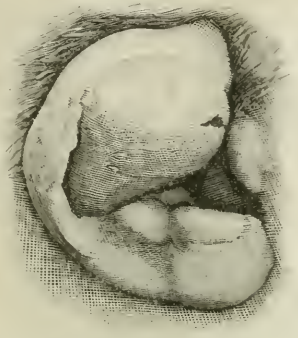

Fig. 8.

the touch. Hearing was unaffected. It was very evident that the patient was in a state of chronic alcoholism, and he was told that treatment would be almost unavailing unless he left off stimulants. The fluid which had again accumulated was now removed by aspiration, and it was determined to try pressure so soon as the necessary dressings could be borne. On October 19th, 21st, 23d, and 30th, improvement was uninterrupted; the fluid removed at each visit was found to be more and more thin and pale, and the quantity less and less. The ear was not so angry in appearance, the outlines of the helix began to show themselves, and the sac diminished in size. The tissues were, however, considerably infiltrated.

The patient now resumed his intemperate habits, with the result of exasperating very much the condition of the ear, the organ becoming much worse after each debauch. Being unable to improve his habits in this regard, the treatment was finally suspended before a cure was accomplished.

Remarks.—In reviewing the four cases above, and the writer's other two cases, viz., Case I. and Case VIII., before given, it will be convenient to arrange them in the following tabular form:

The Author's Cases of Othæmatoma in the Mentally Sane.

No.	Age.	Sex.	Occupation.	Ear affected.	Habits.	Causes.
1...	43	M.	Negro minstrel.	Right.	Temperate.	Trauma.
2...	35	M.	Gymnast.	Left.	Temperate.	Trauma.
3...	43	M.	Lawyer.	Left.	Temperate.	Trauma.
4...	40	M.	Packer.	Left.	Temperate.	Trauma(?).
5...	27	F.	Tailoress.	Left.	Intemperate.	Trauma.
6...	25	M.	Merchant.	Right.	Intemperate.	Trauma.

It will be seen that in five of these cases the cause was traumatic, the injury in one of them being slight. In one case the history in this regard is incomplete. Five were males and one was a female. Hearing was not impaired by the disease in any of them. Four of the patients were temperate and two were intemperate.

Of the ten cases reported by other American writers, the right ear was affected in four, the left in four, both in one, and in one case the side affected is not stated. It will thus be seen that of the sixteen cases occurring in this country, of which a full history is given, and including the writer's six cases, the left ear was most frequently affected. In nearly all of them there was a history of trauma, and where this factor was seemingly absent, as shown by the history, it appears that the parts about the external auditory canal were the seat of inflammatory action, or had been wounded in operative procedures (trauma) consisting of incisions into the cartilage.

One can well believe that "perichondritis" could extend itself from the cartilage of the canal to the pinna in such cases. Gruber mentions two cases where the trouble began in the cartilage of the canal.

Othæmatoma in the insane has its peculiar interest also, and it is believed that the following cases will prove instructive. They were placed under the writer's observation in the New York City Lunatic Asylum.

Case XV.—Female, aged thirty-two; under the care of Dr. E. E. Whitehorne. Has dementia, and is violent. On October 19, 1882, the left auricle suddenly became the seat of a hæmatomatous tumor the size of a pigeon's egg; it was of a dark purple color, and was situated on the outer surface. The swelling impinges on the concha, and occludes the external auditory meatus. Its progress was at first slow, remaining stationary for six weeks, when it again commenced to gradually increase in size without active inflammatory symptoms. There was fluctuation, but no pain; the skin was thickened, movable, and very much less discolored. Outline of helix remains, but antihelix, and fossa obliterated; meatus more free. The posterior surface of the auricle was unaffected. Self-inflicted injury, due to the long-continued practice of violently pressing the ears with her hands, had doubtlessly given rise to the trouble; it was with much difficulty that they were removed from the ears long enough to permit an examination of the parts being made. She always has numerous marks on the chest and elsewhere from self-inflicted injuries. The case progressed favorably from this time on, without any treatment, spontaneous recovery finally taking place.

Case XVI.—Eliza ——, aged thirty, admitted September 30, 1882, with acute melancholia; under the care of Dr. G. H. Gorham and Dr. H. A. Craig. On December 23d slight redness and swelling of the fossæ of the left auricle was observed, the inner surface of the organ being unaffected. On December 24th the concha was invaded, occluding the meatus, and the ear was poulticed. The tumor increased in size until the 28th, when it was as large as a hen's egg. It remained stationary, the poulticing being continued, until the 30th, when it was laid freely open by a horizontal incision, evacuating a blood-clot and bloody serum. The cavity, which was about one and a half inch long by one-half inch wide, was syringed out with carbolized water and afterward packed with oakum and balsam of Peru. December 31st a compress was applied. The outer surface of the auricle now presented a smooth convex surface; the topographical outlines of the cartilage were absent, the concha and lobule even being indistinguishable. The tragus was unaffected, but was in contact with the tumor. The swollen tissues were of a dark purple color. From the wound made by the incision there was constant and profuse oozing of sero-sanguinolent fluid, which trickled down the neck of the patient. The arms of the patient had to be confined to prevent further infliction of self-injury to the ear. Subsequently an abscess formed on the posterior surface of the auricle, and ruptured in that situation, the contents discharging from both anterior and posterior wounds. Gradual healing of the parts took

place during January, the walls of the cyst uniting and the abscess healing by granulation. February 24th ear completely healed. An examination in May showed the existence of considerable thickening in the superior portion of the auricle, with partial obliteration of the concha. The organ is not reduced in size apparently, although it has a shrivelled look, the outlines of the antihelix being distorted. The integument was not markedly adherent, and its color normal.

Case XVII.—Mrs. Barbara K——, aged forty, admitted July, 1883, with acute melancholia. Has delusion that devils are in her head, and hallucinations of hearing. To prevent devils "crawling" into her ears and to exclude annoying voices she thrusts foreign bodies, such as pebbles, rags, and the like, into her ears. On August 6th the whole right exterior ear was observed to be intensely hyperæmic, but not thickened. The meatus externus, however, was occluded by swelling of its walls, and a little pus was found on syringing out the canal. On the 8th the auricle was much more swollen, the markings becoming indistinct. Hot applications were made, and on the 9th pus flowed from the meatus freely. On the 13th it was observed that considerable purulent discharge was escaping from over the superior margin of the concha. Hot fomentations were employed, and the rupture healed by granulation about August 28th, leaving the cartilaginous portion of the external auditory canal occluded, the walls being in contact. The concha and fossa of the helix were obliterated and the tissues indurated; the auricle is greatly thickened and shrivelled. Hearing is unimpaired on this (right) side.

On August 11th the left ear was found to be inflamed also, and some dirt and a small piece of rag were removed; afterward pus escaped. The ear was then treated the same as the right had been. When the symptoms abated the auricle remained thickened, and the canal was much reduced in size. [The clinical history of this case was kindly furnished by Dr. Dent, Assistant Superintendent.]

It will be observed that in two of the above cases there were complications attended with suppuration; in one of them—Case XVI.—this was due probably to contusions of the parts during the progress of the othæmatoma, and in the other case (XVII.) the othæmatoma seems to have been caused by trauma and suppurative inflammation in the external auditory canal.

The treatment of contusions of the ears, of course, attracted the attention of ancient physicians. Thus Paulus Ægenita, in treating of these injuries, did not think any treatment required; since it was necessary, however, to do something, he recommended that a local application of myrrh, aloes, etc., be employed. Hippocrates found that some of these injuries were much more grave in their nature than others, and he seems not to have found their treatment satisfactory. He shows a want of faith in bandages or cataplasms, as he believed that they favored the formation of abscesses and established suppuration; the ear, indeed, seemed to stand in need of such applications less than any other part, and none were sometimes good treatment. When suppuration (effusion?) threatened, there need be haste in making an incision, for *often the matter* (?) *was absorbed again* [italics the writer's]. Were he forced to open it (the tumor?) he preferred transfixion with a cautery, since by means of this method the parts get well soonest, and yet it should be well understood that deformity will ensue and the ear be smaller than the other if thus burnt through. If an incision were decided on it should be freely made on the upper (outer?) side, for, he says, the pus (?) is found to be surrounded with a thicker covering than one would have supposed. After incisions, which may not always be followed by evacuation of mucus (serum?), cataplasms and pledgets are to be avoided. The true nature of othæmatoma was unknown in the time of Hippocrates, and in the treatment of the affection he was probably not aware that a separation of the perichondrium from the cartilage takes place, and that the detached surfaces supply the serum, which he wrongly believed to consist of mucus. The cases which have been given, occurring both in the mentally sane and in the insane, while showing that the affection is obnoxious to both classes, at the same time teach us that the trouble in the latter is subject to influences which usually render its management more difficult than in the former. In the treatment of othæmatoma in the insane it would be well to keep in mind that subsequently to the period of intensest local congestion there is very often, probably, a *decrease* in the temperature of the auricle, which may be due to more or less complete restoration of vaso-motor dominance, a condition scarcely distinguishable to the eye from active turgescence, although to the touch the parts are cold even. Opportunity to test this matter by thermometrical observations has not been afforded me, and I am therefore unable to state the exact degree of depression which probably exists. To pursue this topic further, however, would lead us too far.

Concluding remarks in regard to treatment.—One should not be in haste to interfere in these cases; in general it may be said that the dictum of Hippocrates, namely, that the employment of cataplasms and pledgets are to be avoided, is as safe a guide now as it was in his own day. But while excessive poulticing is to be avoided, there are probably some few cases where hot fomentations or light emollients of various kinds may, when judiciously applied, prove grateful in an auricle highly inflamed. As regards pledgets, however, their employment is always liable to do harm, since they give rise to undue irritation if employed early, and the distention produced by them later on, when thrust into the cyst, prevents the walls of the tumor coming together and adhering to each other. The employment of ointment has not, seemingly, been a favorite mode of treatment, but I have no doubt that belladonna ointment would be beneficial where the cutaneous circulation is languid. In the regressive stage I have found dilute tr. of arnica of service, as in other contusions.

Internally the fluid extract of aconite may be given in small and frequently repeated doses; four or five drops in half a glassful of water is a convenient form of employing the drug; of this mixture a teaspoonful may be given every hour or two, or oftener if required. I have seen throbbing in the tumor and local congestion diminish under this course.

Where suppurative processes arise, as they sometimes do, in the inner portion of the auricle, the postaural region, or contiguous to the cartilaginous canal, the calcium sulphide (Calx Sulphurata of the Pharmacopœia) is indicated.

That these patients should be kept quiet, and usually in a restful attitude, need not be dwelt on here. The self-infliction of further injury, or its production by others, among insane persons, should be prevented. Attention to general health, of course, must not be overlooked.

OTHÆMATOMA IN THE LOWER ANIMALS.

This form of disease is said to affect dogs, an account of its occurrence in whom has been given by Mr. S. Ogier Ward.[1] Wilde states that he observed the trouble in a valuable pointer. I have myself never seen a well-defined case of othæmatoma in a dog, unless isolated hard lumps in the pendant portion of the organ be such. It would seem that some shrinking of the auricle would be produced by perichondritis rather than the "lumps" alluded to by writers.

The cat, it would seem, is liable to othæmatoma, an example of which I was shown by my friend, Dr. E. G. Loring, some months ago. The animal (a male) which was the subject of the trouble was of the Angora strain, and was one year and a half old. He was a fine example of the kind, and, perhaps owing to high breeding, very excitable, not to say wild and uncontrollable.

[1] Loc. cit.

Over two weeks before I saw the case the entire inner surface of the left auricle was swollen out, the affected organ forming a long, pointed tumor. The effusion was gradually reabsorbed, and when the writer examined the ear afterward, it was smaller than the right one, and somewhat thickened and shrivelled. The presence of some cutaneous trouble in the post-auricular region and over the vertex was noted. The auricle had assumed its natural color. Subsequently to the above, Dr. Loring informed me, the right auricle was affected in the same way the left had been. There was no evidence of the auricle having been scratched. The animal has since run away.

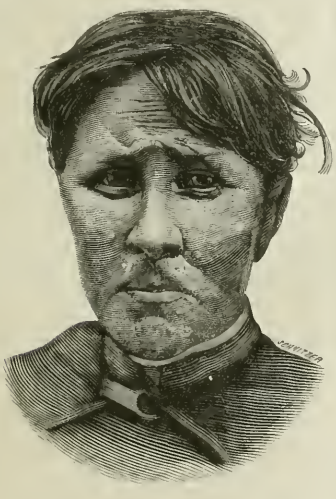
The writer has frequently examined the ears of pugilistic cats with ears deformed by lacerations produced by biting and scratching, but has never before met with an example where deformity characteristic of perichondritis existed.

A CASE OF INDIGENOUS LEPROSY.

By W. H. GEDDINGS, M.D.,

AIKEN, S. C.

Miss ——, twenty years of age, descended from an English family which has resided in South Carolina for several generations, was kindly referred to me for treatment by my friend, Dr. F. L. Parker, of Charleston, S. C. At the age of ten, while in the enjoyment of good health, a white spot appeared on the right leg immediately below the knee, about the size of a ten-cent piece, devoid of all sensation and not rising above the level of the skin.



Three months later a second spot appeared on the left elbow, presenting the same characters as the first, but surrounded by a brownish areola. Similar anæsthetic maculæ continued to appear during the first year of the disease over various parts of the trunk and extremities. During the succeeding year the skin became indurated in circumscribed patches of a dirty yellow or brownish color, and presenting a lardaceous appearance. Unlike the maculæ these infiltrations were not anæsthetic. Simultaneous with their development islets of yellowish pigment appeared over various portions of the integument, at first about the size of a lentil, but gradually enlarging and by confluence forming extensive patches. During the succeeding eight years she remained in about the same condition, but in February, 1882, hemispherical tubercles about the size of a split pea appeared over the face, especially over the eyebrows and chin.

Present condition.— Patient, who is well developed, presents a rather cachectic appearance. The skin, with the exception of a small area over the sternum, is everywhere of a dirty brownish-yellow color, while that over the sternum is abnormally white, presenting the appearance of ordinary leucopathia. The brownish discoloration is evidently due to excessive deposit of pigment, which, appearing as small spots, has gradually spread over the whole body. Over the face are a number of round tubercles of various sizes, the more mature being somewhat larger than a full-grown marrowfat pea. They are distributed over the whole face, but are much more numerous on the chin than elsewhere. On the forehead, especially over and above the eyebrows, may be seen the flattened remains of tubercles, which, according to the patient's statement, had disappeared during a recent attack of fever. These latter give the face the peculiar leonine expression so often observed in leprosy. The skin over the great toes and corresponding metatarsal bones is much swollen, of a dark, dusky red color, and is very painful.

Isolated cases of leprosy have been observed in Charleston and its vicinity for many years, the present being the latest of a series of twenty that have been brought to my notice during the past twenty-five years. This comprises only those cases that I have myself seen or which have been described to me by physicians familiar with the disease. Although more common among the whites, it is by no means confined to that race, one of the patients being a full-blooded negro and several of them mulattoes. Of the above cases four were Jews. In none of these cases was the disease hereditary, although in one instance a mother and her daughter were affected at the same time. In all these cases except the one just mentioned, there was not the slightest evidence of contagion, nor has it ever been deemed necessary to isolate those affected with the disease. When well enough they walk about the streets of the city, attracting but little attention, as the people know from experience that in this country they run no risk of contracting the disease by coming in contact with those affected with it. As isolated cases of leprosy have been observed on the coast of South Carolina for nearly forty years without any apparent increase in the number of cases, it may safely be inferred that there is but little danger that the disease will ever become endemic in this section.

FIBRO-CYST OF UTERUS WEIGHING ONE HUNDRED AND THIRTY-FIVE POUNDS.

By C. C. STOCKARD, M.D.,

COLUMBUS, MISS.

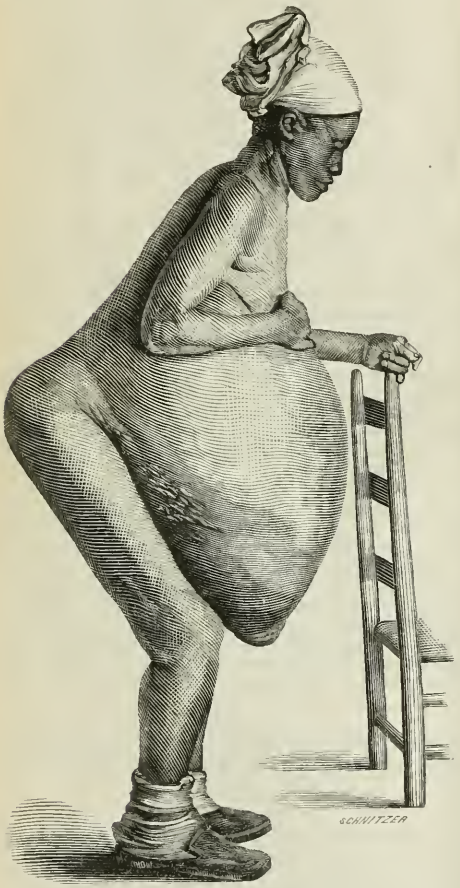
The following case presents some points of interest other than the size of the tumor, which, so far as I can learn, is the largest on record. It is especially interesting from a diagnostic point of view, inasmuch as the physical characteristics of the fluid contents were not those of fibro-cyst, according to Attlee, but were those of ovarian-cyst, according to Drysdale, the post-mortem showing the tumor to be the former.

The patient was a negro woman, aged about fifty years, who was the mother of several children, and had enjoyed good health up to the time of the development of the tumor.

Some twelve years ago, according to her statement, she first noticed a lump in the right iliac region. This continued to grow larger till about seven years ago, when she was seen by two of our physicians, who considered it a case of ascites and tapped her, drawing off several gallons of clear fluid. There was a reaccumulation, and the enlargement had reached its former size at the end of a year after the tapping.

A few years later, as the abdomen became greatly distended, there would occur about once each month an oozing from the right side of the abdomen below the navel, which would continue about a week, and during

this time sufficient fluid would escape to give her considerable relief. During all this time her general health continued good, and she did the work about her house, cooking, etc. Since February of this year there was no more of the oozing, and she suffered so from the distention that she had to give up work and could not get about without help. This was her condition when I was asked to see her on May 2d. I found her truly a wonderful sight.



The abdomen measured in its largest circumference sixty-eight inches, and from the ensiform cartilage to the umbilicus, twenty-seven inches—the navel being a little below the knees, as will be seen in the illustration. The skin in the neighborhood of the umbilicus was thickened, and resembled more the skin of an elephant than that of a human being. The umbilicus was about five inches in diameter and three inches long. Asking two confrères to see the case with me, we decided to tap, to give relief for a while, and the patient was anxious to be tapped. Accordingly, in company with Drs. Mayo, Vaughan, and Sykes, I proceeded to tap her at 2 P.M. May 6th. A few hours previous to this the photograph was taken.

With a many-tailed bandage around the abdomen in the usual way, the trocar was introduced about five inches above the umbilicus in the median line. Withdrawing the trocar from the canula a muddy chocolate-colored fluid flowed, a portion of which was preserved in a clean bottle for subsequent examination. After several gallons had discharged the fluid came quite slowly, and another trocar was introduced four or five inches higher up. From this puncture came a clear, slightly amber-colored fluid, which the patient said was like that drawn at the preceding tapping. After running from this canula some little time it ceased, and the canula being partially withdrawn was pushed into another cyst, which also discharged the clear fluid. After the flow stopped from the first canula introduced, it was withdrawn and inserted about six inches above the second.

The tapping lasted about two and one-half hours, and eight gallons and seven pints of fluid was withdrawn—a considerable amount remaining, which, with the solid part of the tumor, left the abdomen still quite large. Neither of the two kinds of fluid coagulated on standing, even for several days. The colored fluid had a specific gravity of 1.021, solidified on boiling, and under the microscope showed blood-corpuscles, granular masses, an abundance of beautiful cholesterine crystals, and what I considered to be the ovarian cells of Drysdale. Not being an expert with the microscope, however, I would not insist that the Drysdale cell was present, and I regret that I did not send a specimen of the fluid to Dr. Drysdale for examination.

The specific gravity of the clear fluid was 1.015. On adding nitric acid, a drop at a time, a coagulum the size of a drop would sink to the bottom till the whole solidified. This fluid contained also cholesterine crystals and the cells which I supposed to be ovarian.

The patient began coughing immediately, but with this exception was quite comfortable for a few days, when a profuse watery diarrhœa set in. This was checked, but she continued to grow weaker, till death occurred of exhaustion, on the sixth day after being tapped. For three days after the tapping fluid discharged from the points of puncture, saturating clothing and bedding several times.

Post-mortem examination was made two hours after death occurred, before there was rigor mortis. Incision through the abdominal wall and peritoneum showed a network of veins over the surface of the tumor, some of them so large that we took them at first glance for intestines adherent to the tumor. The tumor with the uterus and ovaries was removed and the abdominal incision was closed, as this was all that was agreed to by the family.

The liver was seen to be considerably enlarged—would have weighed, I suppose, eight pounds. The tumor was attached by a pedicle, about an inch in diameter, to the posterior portion of the fundus uteri, and around the pedicle the wall was some two and one-half or three inches thick, and got gradually thinner.

As Dr. Prudden, the Curator of the Museum of the College of Physicians and Surgeons, where the tumor now is, has promised to present it to the New York Pathological Society, I will leave a full description of it to him.

Besides the main tumor there was a fibroid in the uterine wall about three-fourths of an inch in diameter, a small polypus in the uterus, and a cystic tumor of left ovary. Besides these, Dr. Prudden writes me, there was in the left Fallopian tube an encapsulated fibroma, four millimetres in diameter, and a small cyst of the broad ligament. The solid portion of the tumor weighed fourteen pounds, and the fluid, weighed at the same time, twenty-four pounds, which, with the seventy-one pounds drawn at the tapping, make one hundred and eleven pounds. That which escaped after the tapping, with considerable that was lost during the post-mortem examination, at a low estimate, was three gallons, or twenty-four pounds; so that I feel confident the entire tumor with its contents, as it was before the tapping, would have weighed one hundred and thirty-five pounds or more.

The Lehigh Valley Medical Association will hold its annual meeting at Mauch Chunk, Pa., on August 19, 1884. Dr. Theophilus Parvin will deliver the annual address.

Reports of Hospitals.

PHILADELPHIA HOSPITAL.

Clinic of JAMES TYSON, M.D.

CHRONIC PARENCHYMATOUS NEPHRITIS.[1]

Gentlemen: Before giving you the history of this patient, I desire to call attention to some of the more salient points in his present condition. In the first place, I ask you to note the extraordinary pallor of his countenance and of his skin in general. This was even more marked when he was first admitted. Another symptom, which some of you may have noticed already, is œdema. There is a translucency of the skin which, even if you did not know that the limbs were larger than natural, would lead you to suspect that there was effusion into the subcutaneous connective tissue. This would be confirmed by the effect of pressure, which produces a deep pit, continuing for some time. This œdema affects the feet, legs, and thighs, and to a less extent the hands and face. It also affects the abdominal walls. While on this point I shall examine to see if there is any effusion into the peritoneal cavity. There is no fluctuation and no dulness on percussion. These two symptoms, pallor and œdema, are the only ones that are exhibited in a superficial examination.

The history which we have obtained from him is as follows: He is forty-two years of age; was born in Ireland, and has been employed around stables most of his life. He was admitted to the hospital on September 12, 1883. His family history seems to be good. He has been temperate, and has no history of venereal disease, having married early. He has been suffering from his present ailments for two years. In the commencement of it he caught a cold, followed by a little dry cough, which has since passed away. One year ago he noticed that he was swelling—his face, and subsequently the legs and body. This is significant, that, although he dates his present illness two years back, yet he did not notice the swelling until one year ago. Even then, although he did not feel well, he continued at his work. He suffered also from nausea, dizziness, and defective vision on admission, but these include all that is essential in his condition before admission. One more fact, however, should be stated. He had diphtheria in the beginning of his sickness. This may be of some importance in connection with the etiology of his disease.

As we have before seen, the most evident symptoms are pallor and swelling. The swelling began in the face and hands, and this fact suggests at once a cause for it. Given a case of general œdema, we find that it either begins in the lower extremities, in the face and upper extremities, or it begins in the abdominal cavity. These facts are cues to the place where we should first look for the disease. It may be laid down as a general rule that œdema, beginning in the lower extremities, is due to cardiac disease; beginning in the abdominal sac, to hepatic disease; and beginning in the face, to renal disease. This is not an inflexible rule, but it will often save time in the investigation of a case. Adopting this rule in the present case, we should expect to find the cause of the trouble in the kidneys. Hence an examination of the urine is suggested. The test I employ in your presence is the simplest, and under ordinary circumstances is sufficiently reliable; I boil the urine and add a little acid to dissolve any phosphates that may be precipitated. It will be found that the albumen will be precipitated at a lower temperature the greater the amount—that is, if there is large albuminuria the albumen will begin to fall at a lower temperature than if the amount is small. You observe that a copious precipitate has formed. It is scarcely likely that so large a deposit could be due to the presence of phosphates, yet I have known urine to be as opaque as this simply from the deposition of phosphates, so that it is never safe to omit the addition of an acid. This precipitate does not dissolve.

This, then, is a case of albuminuria as well as of dropsy, and a case of large albuminuria. Is this sufficient to show that there is renal disease? I believe that, except where there are evident quantities of blood or pus in the urine, there is no one of the various causes which produce albuminuria which will give such a large precipitate of albumen as we have here. I have no doubt, therefore, that this is a case of some form of Bright's disease. At the same time, it does not do to stop here. We are not satisfied to-day with simply learning that the patient has Bright's disease, but we desire to know what form of the disease he is suffering. We have examined this man's urine microscopically and found a large number of casts. These casts are of a peculiar kind, and through their age we are enabled to be absolutely certain as to the diagnosis.

As to casts, let me briefly call attention to what they are and how they are formed. They are molds of the uriniferous tubules, and are formed of an albuminous material which coagulates after it has been filtered from the blood-vessels into the tubules. This material having been poured out, entangles whatever it may find in the tubule. If the epithelial cells are loosely attached, these are embedded in the material. After a time, the cast shrinks and becomes smaller than the tubule, slips out and appears in the urine as an *epithelial cast*. If, on the other hand, the uriniferous tubule has its epithelium closely attached, the cast slips out, leaving behind the epithelial cells, and appears as *a hyaline cast of small diameter*. This is the most favorable form of casts, being found with the least departure from health, as in congestion. Again, it constantly happens that the tubule is entirely bereft of its epithelium, and then if the albuminous material is poured out its diameter is measured by that of the lumen of the tube plus twice the thickness of the epithelium cells. It slips out and we have *a hyaline cast of large diameter*. These occur in chronic forms of Bright's disease, where the epithelium is stripped off and we have an empty tube into which the material is poured. If, instead of the epithelial cells being loosely attached and slightly degenerated, there happens to be blood, as there often is, in acute inflammation of the kidney, these corpuscles are imbedded in the cast, forming a *blood-cast*. If the cells lining the tubule have undergone complete fatty degeneration and have become filled with fat-drops, or the degeneration has even gone further, so that the cells have broken down and free fat-drops and fatty cells become imbedded in the cast, it passes out in the form of a *fat- or oil-cast*. These of course indicate advanced degeneration of the kidney, or rather of the kidney-cells. This is the form of casts which we find in the present instance, and in addition to them, free oil-drops and fatty cells; these latter are evidently from the kidney. It is not always easy, and indeed it requires a considerable experience to recognize a renal cell which is slightly altered; but there is no cell from any other part of the genito-urinary tract which exhibits the characteristics of this fatty cell, so that when fatty cells and free oil-drops are found it may be concluded that they come from the kidneys.

These are the facts on which the diagnosis is based: the presence of œdema, which started in the face and hands; the existence of a large amount of albumen and fatty casts, and free fatty cells and fat-drops on microscopical examination.

In this case we are able to infer with considerable certainty, what is not always possible, the form of kidney disease present. This is a case of chronic parenchymatous nephritis. This means that the disease affects the parenchyma of the kidneys or the tubules—the essential secreting substance of the glands or the parenchyma, as

[1] A clinical lecture delivered at the Philadelphia Hospital, by James Tyson, M.D., one of the physicians to the hospital and Professor of General Pathology and Morbid Anatomy in the University of Pennsylvania.

distinguished from the blood-vessels and intertubular connective tissue. At the same time there is, strictly speaking, no such thing as chronic parenchymatous nephritis in the true etymological sense of the term. There is an acute parenchymatous nephritis, because there is an acute inflammation which in the beginning involves nothing but the uriniferous tubules. The acute disease, however, cannot continue long before the interstitial tissue becomes involved. This stage, I believe, has been reached in the patient before us, and in every instance of chronic parenchymatous nephritis. The more correct term would be diffuse nephritis, because we have involved not only the parenchyma and the proper secreting substance, but also the interstitial connective tissue, probably not excepting the adventitia of the blood-vessels. There are even some cases of acute catarrhal nephritis which are diffuse, in which it seems that simultaneously both elements of the kidneys are involved. On the other hand, there are cases in which the interstitial connective tissue is the starting-point of the disease, and the tubules are only secondarily involved. This is what is known as interstitial nephritis.

This, in a few words, is the morbid anatomy of this man's kidneys: They are large, pale, and very white. If the capsule is stripped off, there will probably still be found white points scattered over the surface of the organ. It is the size and color of this kidney that have given it the name of the large white kidney. This white color is due to two principal causes. In the first place, to the fact that many of the cells have undergone fatty degeneration, and, as you know, fat by reflected light gives a white color. The little white spots before mentioned indicate that in them the degeneration is more advanced. Tissue from these spots will show the uriniferous tubules filled with oil-drops, and no epithelium cells can be detected. In the second place, an important cause of the white color is the bloodlessness of the organ. The fatty degeneration of the cells is accompanied by an increase of their number, and the tubules become choked with them; and this with the overgrowth of connective tissue causes pressure of the blood-vessels, producing marked anæmia.

A word in regard to the etiology of this form of chronic parenchymatous nephritis and diffuse nephritis. The most frequent causes are scarlet fever and diphtheria, which produce the acute form, which is very prone to run into the chronic disease. Any of the infectious diseases may produce it. But it may also arise *de novo*. I have called attention to the fact that this man had diphtheria, but I stated that it was impossible to say whether or not this was the cause of the nephritis. We have no data to judge from. When we come to look for the causes of chronic parenchymatous nephritis arising *de novo*, they are not easily found. One of these causes is no doubt long exposure to malaria; not a brief exposure but the living for some time under the influence of a decided miasmatic influence. Exhausting diseases, like consumption, will also produce this affection. Formerly it was thought that the only form of kidney trouble resulting from exhausting disease was amyloid degeneration, but it is now known that these diseases often cause this form of Bright's disease. Another cause is perhaps long-continued exposure to cold and wet, especially if the feet are continuously wet. Acute inflammation of the kidney is frequently produced in this way. There are, however, many cases in which a cause cannot be discovered.

Given this condition, what is the prospect of recovery and what shall be done for the cure of the disease? This is a form of kidney disease in which very much can be accomplished by a judicious treatment. There is a most unfortunate popular error in regard to the prognosis of kidney disease. To most persons to be told that they have Bright's disease is, as it were, a death-knell; but I would much rather have renal disease than have consumption. The prospect of cure is more reasonable, while the disease is less unpleasant to other people. The popular notion that kidney disease is incurable is erroneous. Some cases cannot be cured, but many of these could have been, had they come under treatment earlier. There is an important fact in the pathology, on which improvement in this disease depends. The large white kidney sooner or later undergoes contraction, from the contraction of the interstitial connective tissue, and this is a favorable change. Of course this is not recovery. It is really going on to a form of renal disease in which recovery is less likely to occur, but it is a condition more compatible with life. In chronic parenchymatous nephritis the urine is diminished in quantity and of low specific gravity. When contraction takes place the urine increases in quantity, although the specific gravity may still remain low; the amount of albumen diminishes and all the symptoms assume a more favorable character. If a case has lasted a long time, we look for this method of improvement rather than a cure by removal of the diseased tubules and the overgrown connective tissue.

What is the proper *treatment?* There is one thing that must be done immediately, that is to put the patient to bed. You cannot expect any improvement, except in rare instances, unless the patient is put to bed. If this is done the patient, often in the course of a few days, assumes a better appearance, the albumen diminishes, and the appetite improves. Whatever else is done will depend upon the symptoms. If there is dropsy, it should be removed. A diuretic will probably be required. The best diuretic in these cases is digitalis. It may be given in the form of powder, infusion, or tincture. The infusion has the reputation of being the best form, and it is probably a good one, but not better than the freshly prepared tincture. The reason that the infusion seems to act better than the other preparations, is probably because it is given in so much larger doses. It is not infrequent to hear of a tablespoonful of the infusion being given, while only one grain of the powder or ten drops of the tincture are prescribed. A tablespoonful of the infusion is equivalent to three and three-fourths grains of digitalis, while fifteen drops of the tincture are equivalent to one grain of the powder. When I began to practice medicine, five drops of the tincture three times a day was the universal dose. I very rarely begin with a less dose than fifteen drops of the tincture, or one grain of the powder three or four times a day for an adult. If I use a smaller dose it is on account of the sensitiveness of the stomach. In determining the dose of digitalis and of other remedies, I am influenced to a certain extent by the size of the patient. There is no doubt that a man weighing three hundred pounds requires a larger dose than one who weighs only one hundred and fifty pounds, for the same reason that an ox or a horse requires a larger dose than a man.

I ordered this patient fifteen drops of the tincture of digitalis, four times a day, but the improvement was not rapid. The nausea was not increased, but the dropsy did not lessen. I felt that something more was necessary. I therefore gave him a jaborandi sweat, which is often a most valuable measure in this disease. A favorite method of administering jaborandi in this house is by enema. To an infusion of two drachms of the powdered leaves a pint of hot water is added. Of this one-half is first injected into the bowel, the remainder in half an hour, if sweating does not occur earlier. The lower bowel is very tolerant of the drug, and the stomach is thus saved, although the infusion may also be administered by the stomach. In this case the sweat was most successful. Not only were the bedclothes saturated, but large amounts of water also came from the mouth. Occasionally the bowels are acted on and the urine increases in quantity. After this single sweating, the dropsy diminished more rapidly; the urine increased in quantity. When first admitted, the proportion of albumen was one-half the bulk of the urine. It is now

hardly half. Often the albumen does not begin to disappear with the improvement in the other symptoms. In regard to other means of giving jarborandi, when patients are comatose or in convulsions, it must either be given by injection into the bowel or hypodermically, in the form of the active principle, pilocarpin. The latter is really the most elegant method. One-fourth to one-half a grain will usually produce the desired result. I generally give one-fourth of a grain, and if the patient does not sweat in fifteen minutes repeat the dose. If the symptoms are urgent, I sometimes give half a grain at the first dose. Another good remedy is the fluid extract in doses of a teaspoonful every half hour until sweating is produced. Sometimes only one sweat is required, sometimes it has to be repeated every other day or once a week. Jaborandi does have the effect of producing a feeling of prostration. But I have never seen any harmful results. Some writers have laid a great deal more stress on this point than I think it deserves. I think that the prostration is due only to the drain from the system and not to any specific effect. It is the prostration which follows any form of sweating.

Often the digitalis, which has previously failed to act, will immediately show its effects after a jaborandi sweat. The amount of serous effusion is sometimes so great that the vessels are so pressed upon that they cannot absorb. The patient sweats, the pressure is removed from the blood-vessels, and the remedy taken into the system. The same thing follows another mode of treatment which is often valuable—purgation. It is sometimes necessary to clear out the bowels before diuretics will act. For this purpose elaterium is often selected, because it has the property of producing watery stools. It may be given in doses of from one-tenth to one-sixth of a grain. Blood-letting acts in the same way. I recollect a case which occurred in my wards several years ago. A patient had been receiving large doses of digitalis which had failed to act. For some reason in my absence the resident physician bled the man. The digitalis immediately began to act; in half an hour the pulse was down to forty per minute. It would seem as though the medicine had lain away somewhere, either unabsorbed or inactive. While speaking of blood-letting, let me say that in the coma or convulsions of Bright's disease, blood-letting is often of decided benefit. I sometimes employ this remedy, and I believe it would be well to employ it more frequently.

There are other measures to be employed to improve the quality of the blood and counteract the effect of the disease on the system. As soon as the stomach will admit it the patient should receive iron in full doses. The best preparations are those in which the iron is combined with a vegetable acid, as the citrate, tartrate, and acetate of iron. The well known Basham's mixture contains the acetate of iron. The solution of the acetate of iron is now officinal, but it may be prepared according to the following formula :

℞. Tinct. ferri chloridi..... ʒ ij.
Ac. acet. destillat..... ʒ ij.
Curaçoæ..... f ʒ j.
Liquor ammoniæ acetatis..... ad ʒ vj.
Misce.

The dose of this is a tablespoonful.

Easily assimilable food should be given. One of the best forms of food is milk, but its use is not so important in this disease as in interstitial nephritis. The milk should not be too rich. A poor milk or skim milk is more suitable ; too much nitrogenous matter must not be given. There is no doubt that an excess of nitrogenous food is hurtful in all forms of Bright's disease. We now know that the urea is derived almost entirely from the food which is eaten. The old view was that it was the result of the wear and tear on the tissues. But just as the ashes of a steam-engine are derived from the fuel put into the fire-box, so is the urea derived from the food placed in the stomach. Eggs are not suitable food for cases of Bright's disease, nor is butcher's meat. I would not exclude animal food altogether. Oysters, fish, white meat, and game may be allowed. In reference to eggs, there is no doubt that too much albumen in the blood is irritating to the kidneys. It has been proven by experiment that when large amounts of albumen are injected into the blood, the amount of albumen excreted exceeds that which was introduced. This shows that something more must have been added, and this must have come from the blood. Highly albuminous food should therefore not be given.

An interesting question is as to the cause of the anæmia. The common impression is that it is due to the drain of the albumen from the blood ; but the fact is that the quantity of albumen excreted, even in large albuminuria, is very small ; and while it may contribute a little to the anæmia, its effect must be very slight. The amount of albumen passed in the urine throughout a week would be made up by that contained in one pound of beef. In fact the anæmia is partly due to insufficient assimilable food. There is often nausea which prevents the patient from taking a sufficient amount of food. It must be admitted, however, that the loss from the blood contributes somewhat to the effect. Albuminuric patients should be clothed in woollen garments, because they are peculiarly sensitive to cold.

It sometimes happens that the patients get well up to a certain point. The dropsy passes away and all the symptoms except the albuminuria disappear. The question now arises, Is there anything which will directly influence the quantity of albumen ? I do not believe that there is anything that will do this except the gradual relief of the circulation. I have tried astringents, tannic and gallic acid, and the astringent salts of iron, but without benefit. Benzoic acid has been recommended. Fuchsin, one of the aniline dyes, has been said to act in this way. I have given it until the secretions were stained by it, but without any effect in diminishing albuminuria. These things get their reputation in cases in which relief has followed after their administration as a matter of coincidence rather than as a result. Thus a pregnant woman has albuminuria, and immediately after the birth of the child the quantity of urine increases and the albumen diminishes. If benzoic acid or some other drug was being taken at this time, a careless observer would be likely to attribute the improvement to the drug. The only way to influence these albuminurias is to improve the circulation in the kidneys, and this occurs gradually through the restorative powers of nature, aided by such adjuncts as the physician can bring to bear. A method which I have lately used to a considerable extent, and with some success, is the use of gentle but persistent counter-irritation over the region of the kidney, drawing the blood to the surface into the branches of the lumbar arteries which connect with the renal arteries. It is not easy to produce gentle and persistent counter-irritation. The only way in which I have been able to do this has been by means of weak mustard plasters, prepared with molasses or white of egg. Made in this way the plaster does not burn so much and may be worn constantly, or nearly so ; for this is necessary, that the irritation should be persistent. Under this treatment the albumen gradually diminishes and sometimes disappears altogether, when all other measures fail to influence it.

Unusual Susceptibility to Small-pox and Vaccine.—Dr. W. Thornton Parker, of Fort Union, N. M., writes : "Among the recruits lately arrived at this post is a man who was vaccinated successfully when two years of age. Soon afterward he contracted small-pox, and in May of this year was again successfully vaccinated.".

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 16, 1884.

THE INTERNATIONAL MEDICAL CONGRESS.

CABLE despatches up to the hour of our going to press state that the eighth session of the International Medical Congress was formally opened on Sunday, August 10th, at Copenhagen, Denmark, by the President, Professor Panum, of Copenhagen, who delivered an address of welcome to the members, the King and Queen of Denmark, the Council of State, and the King and Queen of Greece being present. The attendance was large, comprising over three hundred Danes, one hundred Swedes, about one hundred Norwegians, and nearly eleven hundred medical men of other nationalities. America was fairly represented, as was also Great Britain, France giving the larger proportion of the latter number.

The scientific work of the association was duly inaugurated on Monday and was divided into that of general sessions and meetings of sections. Considering the amount of material announced and the lack of an understanding as to a definite programme of proceedings, there was at first considerable difficulty in settling upon a systematic arrangement and order of subjects; but the sessions, general and special, as will be seen, were kept well employed and were well attended.

It is impracticable at this stage of the proceedings to give a full account of the doings of the Congress, it being still in session as we write, but the accounts received thus far show how much of strictly scientific work was done. In our next issue we hope to publish still fuller cable despatches, with such addresses received as shall be deemed interesting to our readers. Our arrangements with our correspondent at Copenhagen are as perfect to this end as has been possible to make them, and we trust to our ability in giving the earliest authentic accounts of the work of the Congress obtainable on this side of the Atlantic.

It has been announced that the session will close on Saturday, after a full week of work, and we have reason to expect that the summarized results will be of sufficient interest to our readers to warrant the necessary pecuniary outlay for cable despatches necessary to the fulfilment of our promise.

It is quite probable that the next congress will be held in America, as the invitation on behalf of the medical profession here through the American Medical Association has been favorably received, and will doubtless be acted upon accordingly. No definite action has yet been decided upon up to our present advices.

THE DOCTOR IN FICTION.

IT is to be presumed that doctors are gratified to find that novel-writers have of late taken them up so largely. Few of the more prominent novelists have now left us untouched. The late Mr. Charles Reade has recorded the wonderful deeds of a medical woman, in order to prove to the dull-eyed public that medicine was an art in which the gentler sex could shine. Mr. Howells has introduced his "Dr. Breen," and has therein shown that the general tendency of women, however medically inclined, is to collapse on the matrimonial rock. Miss Phelps some time ago tried to portray an impossible creature who was called "Dr. Zay." She was described as being lovely, scientific, and homœopathic. By virtue of the first two qualities she cured a patient, and subsequently became his wife. We do not know what lesson Miss Phelps sought to inculcate—if any; but it strikes us that to try and make something heroic out of that last outrage upon common-sense—a homœopathic woman—is a great waste of talent.

Mr. Henry James has given an excellent portrait of a New York fashionable physician, in his "Washington Square." More recently he has been marrying a young American doctor to "Lady Barbarina," the daughter of an English peer, and showing the effects of the union of American medicine with English aristocracy. The result is not a happy one to the contracting parties, and the young doctor is obliged to take down his sign, give up his researches into cerebro-spinal meningitis, and live in London with his mother-in-law. We are informed incidentally of the peculiar absence of social position which the average English doctor is accorded by his hereditary legislators.

We cannot say whether Mr. Cable, in his "Dr. Sevier," is writing a novel which is to solve some social problem or simply to portray a unique character. Doubtless our Louisiana colleagues can better appreciate his work.

In a recently published novel, entitled "A Country Doctor," Miss Jewett brings up again the question of women and the study of medicine. It must be confessed that her novel, though somewhat prolix, deals with the subject at issue in a way that commands respect. Her heroine is a young woman who is brought up under the tutelage of a "country doctor," himself a charmingly and truthfully drawn character. She feels as she grows up that she possesses an especial fitness for practising medicine, and an overwhelming certainty that she is not like other women. She wants to practise medicine, not to be a wife and mother. Her trial comes when she falls in love with a not over-brilliant young man. After a hard struggle she gives him up, and makes the Hippocratic oath have something of the significance of a conventual vow.

It is not improbable that there are some such women as Miss Jewett portrays, women who have a certain instinctive aptitude for making sick people feel better, and who can follow out this aptitude better as doctors than as nurses. Their number is naturally very small. In "A Country Doctor" their feelings and ambitions are well shown. Here is none of the namby-pamby transcendentalism, the globules and matrimony of "Dr. Zay."

THE PATHOLOGY OF OBESITY.

PROFESSOR EBSTEIN'S monograph upon the treatment of corpulence has excited a large amount of attention from the medical profession, and has called forth a considerable number of articles upon the same subject. American physicians do not meet so many cases of obesity as do their European *confrères*. Nevertheless, the disease exists here, and it will be worth while for our readers to keep themselves acquainted with the progress made in our knowledge regarding it. Probably most physicians who have tried to reduce obesity by prescribing the regulation anti-fat diet have been disappointed. Doubtless this is often the fault of the patient or the environment; but one cannot resist the conclusion that, aside from all extraneous considerations, anti-fat diets and Bantingism generally are often inherently inefficient. The very fact that Ebstein's work has been so eagerly read points to this same conclusion. Ebstein has certainly furnished the profession with some valuable and practical hints in this direction. But it is yet too soon to say that his new diet of fat and nitrogenous food is to be any more successful than earlier ones. We have already expressed the opinion that theoretically it has but feeble support, while, practically, it is known that Voit has actually fattened animals with fatty and nitrogenous food. Leaving this question for the future to decide, therefore, we would now call attention to an interesting review of the subject of obesity, or morbidly great corpulence, which Professor Kisch, of Prague, has recently contributed to the *Deutsche Medizinal Zeitung*.

In normal conditions there is a tendency for the deposit of fat in the connective tissue of certain regions, such as the subcutaneous tissue—especially of the abdomen and buttocks—also in the mesentery, omentum, regio pubis, beneath the pericardium, about the large vessels—especially the renal vessels—in the orbit, etc. On the other hand, there are a few places where fat is never present, as for example in the lids and the male sexual organs. The estimates of the normal amount of fat in the adult vary greatly. Kisch gives it as one-twentieth the weight of man and one-sixteenth the weight of woman. This normal amount reaches its height in men at the age of forty, in women at the age of fifty.

The influences which produce obesity are numerous, and the endeavor of Ebstein to reduce them in most cases simply to errors of diet and exercise will hardly succeed. Obesity not unfrequently attacks children before puberty, being the expression of anæmia, chlorosis, faulty living, and heredity. But it is generally at a later age that the trouble comes on. It is, no doubt, a fact that a full diet containing an excess of non-nitrogenous food, the use of alcohol, and sedentary habits are the most frequent exciting, if not primary, causes of obesity. As we have said before, the question whether fat is a pathogenetic factor in producing fatness must, in view of Ebstein's positive statements, remain for the present unsettled.

Women are more subject to obesity than men, a fact that is easily explained in view of their more sedentary life, their inclination to non-nitrogenous foods, and perhaps to the lesser activity of their sexual life. For it seems quite certain that the active exercise of the sexual function is an element in preventing accumulation of fat. We ought to mention, however, that Professor Ebstein discredits this—and the Professor has been obese himself if we are rightly informed.

There is a certain tendency to corpulence which is racial. Among the English and Germans there are more fat men and women than among the Celtic, Gallic, Latin, or American races. The Bushmen and South Sea Islanders are inclined to take on fat, while the North American Indian is proverbially fatless. In Mr. Herbert Spencer's Social Statics are many interesting facts concerning this racial obesity or leanness.

Most of the stories regarding excessively fat people are exaggerations. The fattest person whom Kisch has ever seen weighed only 385 pounds. The celebrated Daniel Lambert is credited with weighing 52 stone 11 pounds. A man named Ed. Bright is quoted by Dr. Copeland as weighing 608 pounds. Erchenmayer cites the case of a girl, ten years of age, who weighed 219 pounds. Most of the Dime Museum fat people weigh considerably under 400 pounds, and it is very doubtful if that limit is often exceeded by human beings of ordinary height.

According to Toldt, connective-tissue cells and adipose-tissue cells are not identical. Toldt believes that adipose tissue is a special fat organ, having a separate and well-characterized set of blood-vessels and an independent nutrition-process which results in the manufacture of fat. Some physiologists look upon adipose tissue as a distinct metabolic organ, and Toldt's view has certainly much in its favor. According to it, we must suppose obesity an abnormal activity on the part of true fatty tissue, combined with a morbid taking on of the fat-making function by ordinary connective tissue.

The pathological changes and the consequent functional disturbances in obesity are of much interest. Professor Kisch has investigated this subject, and contributes some original observations to it.

First, as regards the heart, an organ which is inclined early to show signs of disturbed action. The fatty heart, as distinguished from the fattily degenerated heart, is affected, according to Leyden, in three degrees of severity. In the first there is simply a thick layer of adipose about the organ; in the second, with the fatty deposit there is a softening or relaxation of the muscles, dilatation of the cavities, and enfeeblement of action. In the third form there is combined with the fatty heart an arterial sclerosis. The symptoms in the higher grades of fatty heart resemble considerably those of fatty degeneration, and need not be here enumerated. Kisch has made sphygmographic tracings in four hundred cases of fatty heart with the following result: In thirty-six per cent. of cases there was a *pulsus tardus*; in thirty-two per cent. of cases the pulse varied from one of a slightly to one of a completely dicrotic character; in twenty-four per cent. of cases an increase of tension from arterial sclerosis was shown; in four per cent. of cases there was simple arythmia. The value of these examinations is, of course, slight of themselves. It is to be assumed, though it is not stated, that the patients had no valvular disease of the heart and no kidney lesions.

As regards the respiratory organs, Kisch found in many cases bronchial catarrhs. Naturally such symptoms as dyspnœa, and even pseudo-angina, were frequent.

The digestive organs of the obese are very likely to be deranged. Gastro-intestinal catarrh, dyspepsia, constipation, hemorrhoids are present, and are due partly to dietetic errors, partly to the weakness of the heart and the incapacity or disinclination on the part of the patient to take sufficient exercise. An enlarged and fatty liver is of frequent occurrence, but its existence is not easy to make out by physical examination.

Urates, uric acid, and oxalate of lime are found in the urine. It is well known also that the obese are liable to glycosuria, and Kisch found sugar in the urine of many of his patients at periodic or irregular intervals.

Owing to the increased activity both of the sweat and the sebaceous glands, fat persons are subject to "catching cold" and to attacks of rheumatism. Such skin diseases as boils and carbuncles are relatively frequent.

The bodily temperature shows an inclination to mount up, and in fevers the corpulent burn actively. Their feebler resistance to fevers was first pointed out by Hippocrates. Liebermeister states that they are less amenable to antipyretic measures.

Parallel with increase of fat is a decrease of sexual appetite and sexual power. Kisch found in several cases absolute azoospermia. Women are inclined to amenorrhœa and sterility. Among 215 obese women Kisch found 49 cases of amenorrhœa, 119 of scanty menstruation, and 49 of sterility.

The blood of the obese is poor in red blood-corpuscles. Obesity is, in fact, a disease of diminished and perverted oxidation. There are not only too few red corpuscles, but there is too much water and an excess of fat.

THE EXTRACTION OF FOREIGN BODIES FROM THE BLADDER.

As a general rule, persons who have foreign bodies in their bladders do not apply for surgical relief until some time has elapsed. In many cases this is doubtless due to the fact that they at first suffer but little pain; after a time, however, the foreign body causes cystitis, is covered with layers of phosphates, gradually increases in size, and becomes a source of constant irritation and discomfort to its host. The conditions, therefore, of surgical intervention are widely different according as the foreign body is recent or old. In either case, extraction *per vias naturales* may be very difficult; but it is evident that an old foreign body, which has become the nucleus of a secondary calculus, is peculiarly interesting from the difficulties which it offers.

For a long time it was supposed that a lithotomy operation was imperatively demanded. It is possible, however, to remove it otherwise by two operations: At the first the calculus is crushed by the lithotrite; at the second the foreign body is extracted in its primary condition. Guiard (*Ann. des Mal. Genito-Urin.*, April, 1884) has recently removed a large calculus, the nucleus of which was a hair-pin, from the female bladder by two operations, with very slight inconvenience to the patient. And Dr. Heuriet has recently read a paper, before the Société de Chirurgie, on the application of lithotrity to foreign-body calculi.

As regards recent bodies, their nature, consistence, and form are of importance, and very variable; and these are especially difficult data to obtain, for the reason that patients seem to delight in deceiving the surgeon in all genito-urinary matters. If the body is flexible, as a gum catheter, it may be cut or bent double and drawn out, unless too large for the urethra. If of iron or wood the lithotrite is useless; if friable it may be broken up and taken out piecemeal. Civiale recommended a special instrument for cutting up the foreign body, and then leaving its removal to nature. But while this process might be successful in some instances, there are too many probabilities that some of the pieces may remain to give further trouble.

Removal *per urethram*, then, while often difficult, merits, by reason of its great importance, serious attention. The surgeon should know in what part of the bladder the body is situated, and in what position he can secure it. Heuriet has shown by actual experiment upon the cadaver, that these foreign bodies are governed by what he calls laws of accommodation, as is the fœtus in utero, with, of course, the exception of rounded bodies. From his experiments Heuriet drew the following conclusions: 1. The transverse diameter of the bladder is the most constant; it is the only diameter which persists when the viscus is completely empty, and which, in that state, furnishes a resting-place for foreign bodies, provided they are not above a certain size. 2. As the bladder becomes distended, other diameters are formed and it tends to become spherical. Its transverse diameter then attains its maximum, which is 10 ctm. or more (4 inches). Its vertical diameter continues to increase and may attain excessive dimensions. 3. The maximum of the transverse diameter is almost at an equal distance from the summit of the bladder, whatever may be its development, and the cervical region perhaps a little nearer to the latter. 4. Foreign bodies, quite rigid, and 12 ctm. (4.2 inches) long, can only lodge completely in a distended bladder, and in a vertical or oblique diameter. 5. Bodies 6 or 8 ctm. (2.4 to 3.2 inches) long generally assume a transverse position. It is only when the bladder is full and considerably distended that they may take a vertical or oblique position, or rest on one extremity in the region of the neck. When they have a transverse position they may float, provided their specific gravity and the amount of vesical dilatation permit; but hollow bodies, such as a piece of catheter, almost always remain at the base.

The transverse diameter, therefore, is that which varies least, whatever may be the state of distention of the bladder, being smallest when the bladder is distended and greatest when it is empty. These peculiarities have a remarkable influence on the direction which foreign bodies take, and we know *a priori* that they tend to assume a transverse position. On entering the bladder from the urethra they are situated in an antero-posterior median plane. But after micturition the antero-posterior and vertical diameters are effaced, and the body changes its position; its posterior extremity receives an impulse from the corresponding wall of the bladder which tends to approach the neck. This impulse moves the anterior extremity from the median line, where it was at first, toward the right or left, on account of the persistence of the transverse diameter. At the same time, as the bladder contracts, the posterior extremity is pushed forward by the diminution of the antero-posterior, and

downward, by the diminution of the vertical diameter. Thus the transverse diameter is the only one which the body can assume when the bladder is empty. It may, therefore, be laid down as a rule that *rigid* and *elongated* foreign bodies tend to assume a *transverse* position. But if their dimensions exceed 6 or 8 ctm. they cannot rest in this position, but must lie obliquely.

Those accustomed to vesical manipulations know that the contractions of this organ commence by a raising up of the posterior face and floor. These parts seem to advance toward the neck, leaving two prolongations on each side, which subsequently approach the neck. The neck is the fixed point and all other parts contract toward it, and the diminution of the capacity of the bladder commences by shortening of the antero-posterior diameter, which is followed by shortening of the vertical diameter.

The elevation of the floor of the bladder is a very essential point in enabling the surgeon to grasp a fragment. In cases of enlarged prostate great difficulty may be encountered until the bladder commences to contract, raising the base and thus bringing the body within reach of the instrument. In searching for a body in an empty bladder, it may be impossible to move the instrument save in a lateral direction, and if this cannot be done the operator may be sure that the bladder has not been entered. When, however, the bladder is distended, as by an injection, these conditions immediately change. The foreign body becomes movable, and its position is no longer regulated by physiological but by physical laws. The case is analogous to the state of hydramnios in the pregnant woman. The fœtus simply floats about and has not stable position. Distention of the bladder by injection, therefore, so far from favoring the search for and extraction of the body, really hinders these manœuvres.

News of the Week.

Life !—Dr. S. W. Francis' latest definition is—*Can : Can-Can : Can't !*

The American Dental Association held its annual meeting in Saratoga last week.

Quarantine at New Orleans has been reduced from forty to ten days for ships from infected ports.

The State Board of Health of Kentucky has issued a circular of instructions regarding the prevention of cholera.

Fatal Accident to a Medical Student.—Another fatal accident has occurred in the Alps, the victim being a medical student, son of Professor Bamberger, of Vienna.

Another Grave-robbery near Philadelphia.—Two men, one of them a Dr. J. B. Weider, of Philadelphia, have recently been arrested for grave-robbery at Norristown.

Popularity of the London Health Exhibition.—Upward of one and a-half million have visited the International Health Exhibition during the two months it has been open to the public.

Lepers Returned to China.—The authorities of the city of San Francisco have sent back to China nineteen Chinese lepers, paying their passage and giving each one $5. Nineteen cases lost to science.

The Cholera in the United States.—The probabilities are that the present European epidemic will not be a severe one, and that the cholera will not reach this country until next spring or summer.

Jefferson Medical College.—Dr. Robert E. Rogers, Professor of Medical Chemistry and Toxicology in this institution, has tendered his resignation of the chair, to which he was elected in 1877.

An Italian Doctress.—Fräulein Giuseppina Cattani has recently passed her medical examination at the University of Bologna *cum laude*. Miss Josephine is a pioneer among Italian medical women.

A Dangerous Project.—A St. Louis physician proposes to publish an "Encyclopædia of Medical Wit and Humor." We earnestly urge our respected and ambitious confrère to make it a pocket edition.

An Austrian Cholera Commission.—The authorities of Vienna have sent a commission composed of two physicians and three sanitarians to Toulon and Marseilles for the purpose of investigating the cholera epidemic.

Massachusetts General Hospital.—*The Boston Medical and Surgical Journal* is "glad to state that at the request of the Board of Trustees, Drs. H. J. Bigelow and R. M. Hodges have withdrawn their resignations from the staff of visiting surgeons."

The Successor of Dr. Wm. Pepper.—The *Medical News* states that Dr. William Osler, of McGill University, Montreal, is favorably mentioned in connection with the Professorship of Clinical Medicine in the University of Pennsylvania, lately held by Prof. Pepper.

An Ancient Hospital Confiscated.—The Hospital of Jesus in the City of Mexico is said to have been founded and endowed by the conqueror Cortez. The government has recently confiscated the property on the plea that the terms of the founder's will had not been complied with.

Pasteur's Hydrophobia Vaccine a Success.—The government commission which has been making experiments similar to those of M. Pasteur in connection with finding a preventive for hydrophobia, has reported that its investigations decisively confirm the correctness of the distinguished scientist's theory.

Living Quadruplets.—An apparently authentic account is given of the birth of four living male children by a woman named Mrs. H. W. Pullman, who resides near Eureka, Mo. The mother had previously given birth to triplets, and the husband may well look forward to the next pregnancy with interest.

Hydrochinon—Another Antipyretic.—Dr. Paul Seifert reports upon the antipyretic value of hydrochinon, $C_6H_6O_2$, a benzol-compound resembling resorcin. He finds that it reduces temperature as quickly though not quite so permanently as quinine. It has no irritative or toxic effects. The dose varies from one to four grammes.

The Carnegie Laboratory at Bellevue Hospital Medical College.—Plans for the erection of this new laboratory have been filed and work upon it will soon be begun. The building will be fifty feet square, and five stories high. It will be on East Twenty-sixth Street, on the south or opposite side from the present College Building.

That Office Thief.—Our warning of last week came too late to prevent the robbing of Dr. Francis J. Quinlan's office in West Fifteenth Street. Dr. Quinlan was robbed of clothing, valuable books, and surgical instruments. One of the most aggravating things in connection with these robberies is the stupidity and inefficiency of the city's detective force. We have yet to learn of any case in which they have done anything but look "devilish sly."

What Cholera has done for Russia.—Cholera first appeared in European Russia in 1823, says the *Nowoje Wremja*, and continued until 1838. During this time 500,000 persons were attacked, and 240,000 died (43 per cent.). In the second epidemic (1847–59), out of 2,589,000 attacked, 1,032,000 died (40 per cent.). In the next epidemic (1865–72) there were 326,968 deaths. Altogether cholera has attacked 4,000,000, and killed 1,600,000 Russians.

Specific Directions for Preventing Cholera.—The five points to be looked after in attempts to prevent cholera, as laid down by the Illinois Board of Health, are: 1. The condition of the water supply; 2. The disposition of night-soil, garbage, and sewage; 3. The cleansing of streets, alleys, and other public places; 4. The supervision of food supplies, and of market-places, slaughter-houses, and similar establishments; 5. The general sanitation of every house and its surroundings.

The Cincinnati Board of Health.—Our valued contemporary the *Cincinnati Lancet and Clinic* has for some time been trying to awaken the profession to an interest in reforming the sanitary management of the city of Cincinnati. A year ago the Cincinnati Board of Health was constituted of five saloon keepers and one quack doctor, now it has reformed enough to substitute a street paver for the quack. The medical profession is, however, still not represented at all in the sanitary councils of the city. This is certainly a very anomalous condition of affairs and we trust that the *Lancet and Clinic* will keep at work until some improvement is brought about.

Water and Disease—Sanitary Hydrophobia.—The following two items have recently been put in circulation. The tendency of modern sanitation is apparently to make people afraid of water, creating a kind of sanitary hydrophobia: "Of 142 epidemics of typhoid fever, observed in various localities, in 125 cases the epidemic had no other determining cause than the use of water containing impurities" ("Reports Local Government Board, England"). "If any taint (however small) of infective material gets access to wells or other sources of drinking-water, it imparts to large volumes of water the power of propagating disease" ("Mem. Local Government Board, England, July 13, 1883").

The Epidemiological Society of London held a conference on July 22d. The president of the society, Dr. Norman Chevers, C.I.E., opened the meeting with an address entitled "Health in India," and was followed by Dr. William Squire on "Change in Type of Epidemic Disease." The conference was concluded July 23d, when an all-day sitting was held. The subjects treated were "Leprosy in India and the Best Means of Preventing its Increase," by Surgeon-Major Pringle, M.D.; "The Behavior of Typhus in England during the Present Century;" and "A Consideration of the Present Aspect of Cholera in Europe." The latter subject was opened by Dr. Lawson, Inspector-General of Hospitals, and excited warm discussion among a number of medical gentlemen who were present.

A Discussion on Germ-Pathology and Cholera took place at the monthly meeting of the Newport Medical Society, August 5th. A number of New York and Boston physicians took part, including Drs. W. T. Lusk, Leroy Satterlee, and Dr. H. O. Marcy. The latter gentleman read a paper on the relations of micro-organisms to infectious diseases. He referred to the apparent contradiction between Florence Nightingale, in her communications to the New York *Herald*, and Dr. Koch, in his official letter to the Mayor of Toulon, the one of whom claims that personal contact with cholera was not to be feared, while the other strenuously condemns the possibility of even the slightest risk of personal contagion. Dr. M. argued that the true safety lay in the mean between the two extremes of opinion, and that constant and perfect sanitation, with avoidance of both direct and indirect exposure to the disease were required.

An Attorney-General who Understands Blood-Purifiers.—Time was, says *The Medical Chronicle*, when a gentleman holding in this State the exalted office of Attorney-General, had too nice a sense of the proprieties of his position to descend to recommend, in his official capacity, a quack preparation, as is done in the following communication, which is being extensively advertised in the newspapers: "The State of Maryland, Office of Attorney-General, Westminster, Md., April 28, 1884. Charles C. F. Schroeder, Esq.: Dear Sir—I am personally well acquainted with Dr. J. W. Steele and Dr. Wm. M. Hines. They are practising physicians of this county, of excellent standing and large experience, and thoroughly competent to speak as to the merits of your Iron Tonic and Blood Purifier. Very truly yours, Charles B. Roberts." Our contemporary very justly protests against the prostitution of the Attorney-General's office to any such business as the above.

Cholera and the Académie de Médecine.—At the session of the Académie de Médecine July 22d, a letter from M. Fauvel was read, in which he adhered to and defended his view that the cholera at Toulon and Marseilles was not Asiatic and not contagious. M. Fauvel's views may safely be considered the expressions of obstinate senility.

M. Jules Guérin delivered an address on cholera which was eloquent and interesting, though in some regards rather antiquated. M. Guérin talked of "epidemic constitutions," atmospheric and organic influences, and the evolution of epidemics under certain fixed laws. He thought the contagiousness of cholera a secondary matter, denounced quarantine, and commended the English method of inspection.

Progress of the Cholera.—A temporary increase in the number of cases of cholera at Toulon and Marseilles occurred during the latter part of last week owing to the intense heat and the return of many fugitives. On the whole, however, the violence of the disease has greatly abated in the cities mentioned. The number of deaths occurring daily has rarely exceeded four or five at Toulon and fourteen at Marseilles. On the other hand the disease has undoubtedly gained a firm hold in Southern France and Northern Italy. Many small towns have been attacked with great violence. Thus says a *Times* correspondent: "In the little village of Gignac, near Montpellier, forty cases of cholera have been found, and there have been numerous deaths. The panic there was so terrible that the fathers and mothers of families fled, leaving their little children uncared for. At Vogue, a village of less than eight hundred souls, in the Ardèche, over thirty cases, with seven deaths in the twenty-four hours have occurred. An outbreak of cholera in Algiers is feared. Some of the reports of deaths from cholera in the villages near Toulon are particularly heart-rending. In some of them more people died of cholera in a day than in Toulon during the same twenty-four hours. In Bordeaux there have been three deaths."

Reports state that examinations of the water from the wells and fountains in all the places visited by cholera show the presence of vast numbers of microbes.

The English cholera (cholera nostras) has broken out seriously at Northampton and in villages near Blackburn. Over two hundred were reported sick at one time.

So far as the mortality of the disease is concerned, the statistics of the Pharo Hospital, Marseilles, are instructive. These statistics show that 521 cases of cholera have been admitted, of which 313 ended fatally, or about 60 per cent. This is a high mortality rate for the disease.

A number of changes have been made in the various quarantine regulations: Spain has established a ten days quarantine against infected Italian ports. The Belgian Government has quarantined against all Mediterranean ports. At the port of New York, the Health Officer has issued some further regulations. Vessels on which cholera develops during the voyage to this port will, of course, be detained, the sick removed to the hospital, and the well persons to the Quarantine of Observation. Any cargo of which there is any suspicion will be discharged in Quarantine. The baggage of passengers from an infected district, or section of country bordering thereon, is required of captains to be kept separate from other baggage. Vessels discharging in Quarantine will be thoroughly disinfected before being allowed to come up to the city. The same rules will apply to baggage or cargo shipped from an infected to a healthy port and reshipped here. Vessels with cargoes wholly or in part of rags will not be given pratique if coming from infected ports, and if from healthy ports, satisfactory evidence that they have not been reshipped from infected districts will be required, as well as evidence that they have been collected where no suspicion of cholera exists.

Cheap Quinine.—Physicians should know that quinine is steadily decreasing in price, and has lately been sold as low as $1 an ounce. It is poor policy, therefore, to use the so-called "cheaper alkaloids" when quinine, which is more efficient, costs but little more. The cause of the decline in price is said to be the removal of the tariff, and an over-production on the part of foreign manufacturers. The world's production to-day is estimated at 4,500,000 ounces, of which Germany and Italy manufacture by far the greatest portion. There is considerable made in England, but this is of a superior quality, and its enhanced cost limits its consumption and consequent production. America consumed forty per cent. of the total production, or about 1,800,000 ounces. Prior to the removal of the tariff, 1,500,000 ounces were produced here, but the effect of the removal of the duty has been to decrease the manufacture and make the United States more dependent upon foreign supplies. It is estimated that now not more than 1,000,000 ounces are manufactured in the New World, but this is in part due to the destruction by fire, in Philadelphia, of the works of the largest American producers, who now send their bark to Europe to be prepared for the market. From the East Indies the shipments of the raw material to the United States were over 6,000,000 pounds, of which a very large proportion was shipped to Europe for account of the American manufacturers. Of late years the quality of the product has materially improved, the quinine now sold having not more than from two to five per cent. of the lower alkaloids, while it is but a short time since that quinine having ten per cent. of these was deemed a satisfactory article. This improvement is believed to be due entirely to the better quality of the bark obtained from the cultivated tree.

International Medical Congress.

EIGHTH SESSION,

Held at Copenhagen, Denmark, August 10–16, 1884.

BY CABLE TO THE MEDICAL RECORD.

Sunday, August 10th—First Day.

The eighth annual session of the International Medical Congress was formally opened on Sunday, August 10th, by Professor Panum, of Copenhagen, who delivered the following

ADDRESS OF WELCOME.

After thanking the King and Queen of Denmark, the King and Queen of Greece, and the State Council, he expressed his great gratification at the large audience present, and hoped that the present session of the Congress would tend to advance the science of medicine, and that a broad and liberal spirit, becoming the grand object in view, would characterize all its deliberations.

Sir James Paget followed with a brilliant address, in which he thanked Denmark on behalf of Great Britain for its gift of a princess who was a model prince's wife. He concluded by hoping that the present Congress would be equally successful with that held in London.

Professor Virchow, in behalf of Germany, hoped that the Congress would honor that country by its choice for a future meeting.

Professor Pasteur also addressed the Congress in some general remarks, in which he referred to the cos-

mopolitan character of science, and the impossibility of conforming it to any particular country.

The King and Queen of Denmark, Council of State, and King and Queen of Greece were present. Sixteen hundred members were in attendance; of these eleven hundred were foreigners, including one hundred Englishmen and about fifty Americans.

In the evening

A GRAND BANQUET

was tendered the members. It was largely attended.

MONDAY, AUGUST 11TH—SECOND DAY.

The Congress in its general session to-day listened to the address of PROFESSOR PASTEUR, of Paris, on

MORBIFIC MICRO-ORGANISMS AND VACCINIA MATTERS.

He described his different well-known experiments in the inoculation of rabies by injecting the virus into the veins of dogs, and the results in protection against the evil effects of the bites of rabid animals. He referred to the report of the French Government Commission appointed to investigate hydrophobia, stating that twenty-three dogs had been experimented upon by protection. All had been bitten by rabid animals in June last, and yet all had remained healthy. Of nineteen unprotected animals, similarly bitten, fifteen went mad. It was the intention of the Government Commission to repeat these experiments. In closing he emphasized the necessity of attempting to protect animals only, but if the dogs were protected the disease would be exterminated.

At the meetings of the sections, sixteen in number, the different Presidents delivered their addresses.

MEETINGS OF SECTIONS.

Section on Anatomy.—Papers read: "The Glandular Cells during Activity," by Professor Ranvier, of Paris; "Terminations of Sensitive Cutaneous Nerves," by Professor Merkel, of Königsberg; "Rotary Movements of Forearm," by Professor J. Herberg, of Christiana.

Section on Physiology.—Papers read: "Mucous and Albuminous Matters," by Dr. Hammarsten, of Upsala; "Fugitive Corpuscles," by Dr. R. Norris, of Birmingham; "Coagulation of Blood," by Dr. Wooldridge, of Cambridge; "Oxyhæmoglobin," by Dr. C. Bohr, of Copenhagen; "Glandular Cells," by Dr. Langley, of Cambridge; "Functions of Cutaneous Nerves," by Dr. Blix, of Upsala.

Section on Pathology.—Papers read: "Necrosis of Coagulation," by Professor Weigert, of Leipsic; "Bacterial Inflammation," by Professor Cornil, of Paris; "Jequirity," by Dr. C. J. Salomonsen, Copenhagen.

Section on Medicine.—Papers read: "On Uniform Nomenclature of Auscultatory Signs in the Diagnosis of Diseases of the Chest," by Professor Austin Flint, of New York; "The Blood-Corpuscles in Anæmic and Leucæmic Diseases," by Dr. S. Laache, of Christiana.

Section on Surgery.—Papers read: "The Iodoform Treatment," by Professor Mosetig-Moorhof, of Vienna; On Antiseptics—"The Sublimate Treatment," by Dr. M. Schede, of Hamburg; "The Treatment by Oxygenated Water," by Professor Paul Bert, of Paris; "Permanent Antiseptic Dressing," by Professor Esmarch, of Kiel; "Anæsthetics in Surgery," by Professor Bert, of Paris; "Colotomy," by Professor Bryant, of London.

Section on Obstetrics.—Papers read: "Myomata Uteri by Laparótomy," by Professor Koeberle, of Strasburg; "Supra-Vaginal Amputation," by Dr. Margary, of Turin; "Cæsarean Section," by Professor P. Miller, of Berne, and Professor Eustache, of Lille.

Section on Laryngology.—Papers read: "The Prognostic Significance of the Several Local Manifestations Observed in Tuberculosis of Larynx," by Dr. J. Solis Cohen, of Philadelphia.

Section on State Medicine.—Papers read: "School Hygiene in Denmark," by Professors Hertel, of Copenhagen, and Key of Stockholm, and Mr. Holbech, of Copenhagen.

TUESDAY, AUGUST 12TH—THIRD DAY.

At the general session to-day the address

ON THE NATURAL PRODUCTION OF MALARIA AND THE MEANS OF MAKING MALARIAL COUNTRIES HEALTHIER,

was delivered by Tommasi Crudeli, of Rome. (See next number of THE MEDICAL RECORD.)

INVITATION FOR CONGRESS IN AMERICA.

A communication was received from Dr. Billings, on behalf of the American Medical Association, inviting the Congress to hold its next session in Washington, U. S.

THE WORK IN THE SECTIONS.

In the Section on Pathology, Professor Grancher, of Paris, read a paper on "The Relations of Scrofulosis and Tuberculosis," and Professor Roquemondane, of Limoges, remarked on Ixodes, an almost unknown human parasite.

Section on Medicine.—Professors Ewald, of Berlin, Jaccoud and Grancher, of Paris, presented the subject of "Tuberculosis in its Different Relations to Etiology and Pathology."

Section on Surgery.—Dr. Lewis A. Sayre, of New York, exhibited his plaster-of-Paris jacket, and demonstrated its application. Professor Ollier, of Lyon, read a paper on "Excision and Orthrotomy in Tuberculous Joint Diseases," and Professor MacEwen, of Glasgow, Scotland, presented the subject of "Orthopedic Osteotomy for Genu Valgum and Club-foot."

Section on Obstetrics.—Professor Mikulicz, of Crakow, read a paper on "Antiseptics in Laparotomy." Professor Simpson, of Edinburgh, also read a paper on "An International Nomenclature in Obstetrics," and Professor Halberstma, of Utrecht, on "The Significance of Albuminuria in Pregnant Women."

Section on Ophthalmology.—The following papers were read: Dr. Redard, of Paris, "On the Examination of Vision of Railway Employees;" Professor Rachlmann, of Dorpat, on "Trachoma;" Professor Sattler, of Erlangen, on "The Anatomy of Ciliary Muscle."

WEDNESDAY, AUGUST 13TH—FOURTH DAY.

This day was devoted to excursions in steamers, which included one to the tomb of Hamlet at Elsinore.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 25, 1884.

FRANK FERGUSON, M.D., PRESIDENT, *pro tem.*

DR. FERGUSON reported on the specimens presented by Dr. Wackerhagen at the last stated meeting.

DR. J. H. RIPLEY presented, on behalf of a candidate, a specimen of *Phthisical Ulceration of the Larynx.*

DR. C. H. KNIGHT presented specimens of

NASAL POLYPI,

removed from a patient who gave a history of nasal catarrh of four years' standing, frontal headache, loss of smell, and, for the last six weeks, complete obstruction of the meatus.

The interesting point in the clinical history was with regard to the occurrence of asthma. There was no evidence, on physical examination of the chest, of pulmonary disease. Removal of the polypi had given the patient relief.

DR. W. M. CARPENTER referred to hypertrophy of the nasal mucous membrane as an etiological factor in hay fever, to which attention had been directed by Dr. Roe, of Rochester, and Dr. Sajons, of Philadelphia, and others.

DR. KNIGHT remarked that the symptoms in his case were those of asthma, rather than hay fever, and that the patient had not been a sufferer from the periodical affection known as hay asthma or hay fever.

DR. RIPLEY remarked that the tendency was toward the production of emphysema when there was obstruction to the entrance of air into the air-vesicles.

DR. KNIGHT remarked that probably the condition of obstruction, in his case, had not existed sufficiently long to produce emphysema; at least there was no evidence of its existence on physical examination.

DR. H. N. HEINEMAN presented a specimen illustrating

GENERAL TUBERCULOSIS.

Patient, aged seven months, was admitted to Mount Sinai Hospital June 7, 1884. Father has phthisis. Up to five weeks ago had been well. Then mother noticed frequent chilly appearance, but got better. For the past four weeks has been unusually quiet, and rolled its head. Three weeks ago had slight convulsive seizures, and for some time frequent stools with straining; urine diminished in quantity.

On admission there was frequent respiration, cyanosis, twitchings of both arms (chiefly the left), and a hydrocephalic cry. Seemed to suffer, but was observant. On the succeeding day opisthotonos and conjunctivitis manifested themselves. Depressed fontanelle.

Five days later there was paralysis of the extremities, most marked on right side. Pupils even and contracted. Opisthotonos gone. Died quietly June 22d. The temperature varied between 98° F. and 101.2° F.; was 96.2° F. on one occasion.

Autopsy.—Brain: much serum and pus in pia and beneath it, over the base; some over convexities. The right parietal lobe contained a collection of tubercles, each the size of a French pea, with softened centres, and numbering about twelve in all. The ependyma of the lateral ventricles contained translucent miliary tubercles. The lungs were studded with fine miliary tubercles. The kidneys, spleen, and liver contained miliary tubercles.

DR. RIPLEY asked if the child's lungs were examined before death.

DR. HEINEMAN answered that they were, and that the diagnosis of general tuberculosis was made, from the fact that the father had phthisis and the child gave a history of emaciation, etc., which could not be accounted for readily by the general physical signs. A moderate amount of bronchitis was developed before death, and it was supposed that there was pulmonary tuberculosis. The condition of lungs, as seen in the specimen, would not necessarily give rise to physical signs.

DR. RIPLEY was not prepared to accept the last statement, as when there exists any considerable amount of tubercular infiltration there are not only the physical signs of bronchitis, but there is a change in vocal fremitus and resonance and the pitch and quality of the respiratory murmur.

In a case which he had seen recently, in which tubercles did not exist except in the lungs, he was obliged, in absence of a tubercular history, to make a diagnosis by means of physical signs; there were a few bronchial râles, and decided changes in vocal fremitus, resonance, and respiratory murmur. In a case with so much infiltration as existed in the lungs presented by Dr. Heineman he believed that, as a rule, there was some change in the physical signs mentioned which could be recognized.

The specimen was, therefore, additionally interesting on account of the absence of any such change.

With regard to the temperature in tubercular meningitis, he made an autopsy on the body of a child who died of that disease, and during the last few days of life the patient's temperature was 97½° F. As Dr. Heineman had said, there was, very often, no preagonistic rise of temperature in this class of cases. Dr. Ripley had the records of between fifty and sixty cases of tubercular meningitis, and the temperature had generally been low. The symptoms, he thought, varied somewhat with the extent of invasion of other organs. Sometimes the temperature throughout was as high as 103° F., but, as a rule, it was subnormal, or not higher than 101° F.

In Dr. Heineman's case, the temperature rose to 102° F. and over, and Dr. Ripley thought it quite probable that the general tuberculosis increased the rise.

DR. FERGUSON asked Dr. Ripley if he had noticed any ratio between the amount of exudation and the rise of temperature in tubercular meningitis.

DR. RIPLEY had not definite data on that point, but thought that the temperature was not especially influenced by the quantity of exudation.

The committee appointed to memorialize the late Dr. Willard Parker next offered the following:

IN MEMORIAM—WILLARD PARKER, M.D., LL.D.

It is with deep and unfeigned regret that we record the death of our first acting president, Dr. Willard Parker, who expired on April 25, 1884, at the ripe age of eighty-four years.

He was so well and capable up to a very short time ago that his decease then would have been an unmitigated grief to us, and to all who loved him. But during the last eighteen months of his life the infirmities of age and the pangs of sickness had borne so heavily upon him that our sorrow is greatly subdued in view of the peace which has come upon him. To us is now only left the grateful duty of recording his manifold virtues, his great and honorable services to his profession and to the public, and to express our sincere sympathy to his family.

The New York Pathological Society was founded in June, 1844, just forty years ago, and several years before the London Pathological Society was established. For the first few months of its existence its meetings were presided over by temporary chairmen, elected at each meeting. Near the end of its first year, viz., in October, 1844, the distinguished and lamented Dr. John A. Swett, then the leading medical pathologist of this city, was elected president, and Dr. Parker, who was well grounded in surgical pathology, vice-president.

Ill-health, soon followed by death, prevented Dr. Swett from serving, and we are not aware that he ever filled the presidential chair. But so highly did he appre-

ciate his membership in our Society, that in his treatise on "Diseases of the Chest," which contained a course of lectures delivered at the New York Hospital, he announced himself as simply Physician to the New York Hospital, and member of the New York Pathological Society.

Dr. Parker, our first acting President, was successively re-elected in the years 1845, 1846, and 1847, with little or no opposition, and quickly gave our Society a standing before the medical world which few other men could then have given it. Still he had good material to work with, for during these three years it counted among its members, William C. Anderson,* Daniel Ayres,* John H. Borrowe,* Gurdon Buck,* H. D. Bulkley,* Alonzo Clark, James Crane, Edward Delafield,* Abraham DuBois, George Elliott,* John Forry,* Anthony Gescheidt,* Chandler Gilman,* Middleton Goldsmith, John H. Griscom,* Thaddeus Halstead,* Charles E. Isaacs,* W. W. Jones, William H. MacNeven,* John T. Metcalfe, George A. Peters, John C. Peters, Alfred C. Post, William C. Roberts,* Gustavus A. Sabine, Lewis A. Sayre, John O. Stone,* John A. Swett,* Isaac E. Taylor, Robert Tomes, William H. VanBuren,* Hugh Walsh,* Robert Watts,* James R. Wood,* Dr. Wotherspoon,* and others of like ilk.

Of these thirty-seven early members no less than twenty-two have died (those marked thus, *), and this Society has repeatedly been compelled to go in mourning for lovable and useful men, who could ill be spared.

When Dr. Parker was called to the first presidency he was in the prime of life, just forty-five years of age, having been born in 1800. He was a native of New Hampshire, and had only been six years in this city. But he was already Professor of Surgery in the College of Physicians and Surgeons, and was deservedly very popular, having risen rapidly to the position of one of the foremost surgeons and physicians, and most acceptable teacher and lecturer, not only in the eyes of New York, but of the whole country.

He had been a pupil and assistant of Dr. John C. Warren in anatomy and surgery, had served in several hospitals, and been a teacher and professor of anatomy and surgery in other colleges.

He was an excellent presiding officer, and took a warm, well-sustained interest in the welfare of this Society. Among his earliest services to it was the active part he took, with others, in 1845, in housing it in the College of Physicians and Surgeons, where it has remained until this day, and, hopefully, always will remain, to the honor and credit of both.

It was no small benefit to the infant society to be settled so conveniently for its peculiar work, and at such a small annual expense. This has enabled it to preserve all its records and minutes for forty years; to have them widely published in various journals, and to issue several volumes of its transactions free to its members.

Dr. Parker was always a thoughtful pathologist, rather than a minute pathological anatomist; just as he was a great conservative surgeon and hygienist, rather than a mere operator. Although he had a wonderful knowledge of anatomy and of the principles of surgery, the glamour of even major operations never seemed to have the slightest charm for him. He always appeared to think most surgical operations were unfortunately rendered necessary by the imperfections of medical and hygienic art, greatly aided by the ignorance and obstinacy of patients. He obviously regarded great pathological specimens as so many failures in the treatment of disease. He was always rational, rather than merely empirical, or mechanical, and ever aimed to prevent disease and avoid operations, rather than to drug his patients, mutilate them, or make post-mortem examinations of them.

Still he rejected no aids in the study of disease, and always maintained his active connection with this Society, even when loaded with numberless other cares and burdensome honors, and while laboring so hard, from 1866 down, in the establishment and working of the Metropolitan Board of Health, where his views on hygiene could have full play. He was ever ready to sustain us with his presence and example, and with a strong hand, kindly heart, active brain, and ready purse. Even in the last year of his life, when almost crushed with the infirmities of his great age and the pangs of disease, he delighted to counsel for its welfare and honor, and to review its early history and struggles.

For these and many other things this Society owes a debt of gratitude to the memory of Dr. Parker, which it is not only eminently becoming for it to acknowledge, but which we are only too happy to promptly and frankly render.

To those who knew him in his prime we need not say that we were very proud of our first president as a great and good man, a faithful citizen, an eminent physician and surgeon, a brilliant teacher, and a careful watchman over the public health.

Many of us went farther, and took a justifiable pride in those winning personal and mental endowments which a kind Providence had showered upon him; in his manly beauty and impressive stature, in his attractive, gentlemanly appearance and kindly presence, in his great mental vigor and physical activity, in his exceptionally regular and correct personal habits, in his buoyant and even joyish temperament, in his spotless morality and deep religious convictions, we thought him an embodiment in himself of almost all that is good, useful, lovable, and we are, and all his friends should be, greatly comforted in his loss that these high qualities were at our, and their, service so long, and so far beyond the period of life ordinarily allotted to man, for work and for the comfort of his fellows.

He has gone to join that not small band of our illustrious deceased presidents, himself by far not the least, *quorum pars magna fuit.* His closes, for a time, the list which contains the honored names of Wm. H. Van Buren, Robert Watts, Edmund R. Peaslee, Gurdon Buck, Ernst Kracowizer, James R. Wood, John A. Swett, Erskine Mason, Charles E. Isaacs, Jackson Bolton, David S. Conant, Wm. B. Bibbins, and Henry Van Arsdale.

Dr. John A. Swett, our first nominal president, died at the early age of forty-five years. Dr. James R. Wood, our second president, was born in 1816, and died aged sixty-five years. Dr. Wm. H. Van Buren, our fourth president, was born in 1819, and died aged sixty-five years. Dr. Charles E. Isaacs, our fifth president, was born in 1822, and died aged forty-eight years. Dr. Jackson Bolton, our eighth president, was born in 1815, and died aged fifty-one years. Dr. Robert Watts, our ninth president, died aged fifty-five years. Dr. Edmund R. Peaslee, our tenth president, was born in 1814, and died aged sixty-five years. Dr. David S. Conant, our fourteenth president, died aged forty-five years. Dr. Gurdon Buck, our sixteenth president, was born in 1807, and died aged seventy. Dr. Wm. B. Bibbins, our eighteenth president, was born in 1825, and died aged forty-six years. Dr. Ernst Kracowizer, our twentieth president, was born in 1822, and died aged fifty-three years. Dr. Erskine Mason, our twenty-fourth president, died aged forty years. Lastly, Dr. Willard Parker, our first president, was born in 1800, and died aged eighty-four years.

Thus it will be seen that, with the sole exception of Dr. Parker, none of our deceased presidents lived to be very old men. Only one beside him, Dr. Gurdon Buck, reached his seventieth year. No less than three—viz., Drs. Van Buren, Peaslee, and James R. Wood—died in their sixty-fifth year. Drs. Bolton, Kracowizer, and Watts died respectively in their fifty-first, fifty-third, and fifty-fifth years. No less than six died before they attained their fiftieth year—viz., Dr. Isaacs, at forty-eight; Dr. Bibbins, at forty-six; Drs. Swett and Conant, at forty-five; and the beloved Dr. Mason at the very early age of forty years.

Many of our deceased presidents were always delicate; and many were cut off by sudden and sharp sickness. Dr. Parker came from a long-lived and excellent pre-Revolutionary stock on both sides of his family. He lived upon a farm until he was nineteen years old, and although he worked hard and performed excellent service for the rest of his life, he always took great care of his general health.

Our senior living ex-president, in point of years, is Dr. Alfred C. Post, thirteenth president, born in 1806, aged seventy-eight. Our senior ex-president, in point of service, is Dr. Thomas M. Markoe, fourth president, born in 1821, aged sixty-three years. Then follow Dr. John T. Metcalfe, seventh president, aged sixty-two; Dr. John C. Dalton, twelfth president, born 1825, is aged fifty-nine; Dr. Thos. C. Finnell, fourteenth president, born 1827, is aged fifty-seven; Dr. Abraham Jacobi, sixteenth president, born 1830, is aged fifty-four; Dr. Henry B. Sands, seventeenth president, born 1830, is aged fifty-four; Dr. Lewis A. Sayre, twenty-first president, born in 1820, is aged sixty-four years; Dr. Joseph C. Hutchison, twenty-second president, born in 1827, is aged fifty-seven; Dr. Alfred L. Loomis, twenty-third president, born in 1831, is aged fifty-three years; Dr. Herman Knapp, twenty-fifth president, is aged fifty-two years; Dr. Francis Delafield, twenty-sixth president, born in 1841, is aged forty-three years; Dr. Charles K. Briddon, twenty-seventh president, born in 1827, is aged fifty-seven; Dr. Edward G. Janeway, twenty-eighth president, born in 1841, is aged forty-three years; Dr. John C. Peters, born in 1819, twenty-ninth president, is aged sixty-five years; Dr. Edward L. Keyes, thirtieth president, born in 1843, is aged forty-one years; Dr. T. E. Satterthwaite, thirty-first president, born in 1843, is aged forty-one years; Dr. Ed. C. Seguin, thirty-second president, born in 1843, is aged forty-one years; Dr. George F. Shrady, born in 1837, is aged forty-seven years.

It will be seen that the majority of our presidents have been young men. Dr. Swett was under forty years of age when elected president; Dr. Parker, forty-five; Dr. James R. Wood, thirty-two; Dr. Markoe, only thirty; Dr. Van Buren, thirty-one; Dr. Isaacs, only twenty-nine; Dr. Metcalfe, thirty-one; Dr. Van Arsdale, thirty-seven; Dr. Bolton, thirty-nine; Dr. Watts, forty-nine; Dr. Peaslee, forty-four; Dr. Dalton, thirty-four; Dr. Post, fifty-five; Dr. Finnell, thirty-five; Dr. Conant, forty; Dr. Jacobi, thirty-four; Dr. Buck, fifty-eight; Dr. Sands, thirty-six; Dr. Bibbins, forty-two; Dr. Kracowizer, forty-six; Dr. Sayre, forty-nine; Dr. Hutchison, forty-three; Dr. Loomis, forty; Dr. Mason, thirty-eight; Dr. Knapp, forty-two; Dr. Delafield, thirty-four; Dr. Briddon, forty-nine; Dr. Janeway, thirty-six; Dr. Peters, fifty-nine; Dr. Keyes, thirty-six; Dr. Satterthwaite, thirty-seven; Dr. Seguin, thirty-nine; Dr. Shrady, forty-six years.

Signed by authority, JOHN C. PETERS, *Chairman.*
C. C. LEE.
GEO. L. PEABODY.

LACTIC ACID occurs in sour milk from the spontaneous fermentation of sugar of milk under the influence of casein; this transformation is called *lactic fermentation.* A similar change is produced in dextrine, glucose, cane-sugar, etc., by the action of casein and other protein compounds. It is found in many vegetable products which have turned sour. The sarcolactic acid of flesh and muscle is very sour, and in excess causes rheumatism. It is soluble in ether, alcohol, and water, coagulates milk and albumen, displaces carbonic and acetic acids, and yields salts soluble in water and alcohol. It has been used in dyspepsia in place of hydrochloric acid; and when given in diabetes symptoms of acute rheumatism have appeared which have subsided on stopping the acid. Inflammation of the joints and pericardium have been caused by it in animals. It is useful in all alkaline diseases, including typhus and typhoid fevers, erysipelas, diphtheria, etc.

THE BERLIN SOCIETY OF INTERNAL MEDICINE.

Stated Meeting, June 30, 1884.

HERR LEYDEN, PRESIDENT, IN THE CHAIR.

(Special Report to THE MEDICAL RECORD.)

THE Society having been called to order, the first speaker of the evening was HERR MENDELSOHN, who presented some preparations showing

TUBERCLE BACILLI IN THE URINE AND KIDNEYS.

The patient had suffered for some time from a bladder trouble and incontinence of urine, and died rather suddenly from meningitis. The urine was cloudy, alkaline in reaction, and contained albumen. The urine having been evaporated and the dried sediment stained, the tubercle bacilli were seen to be present in large numbers. Koch, in his latest work on the etiology of phthisis, has described the bacilli obtained by culture as large bodies twisted into multiple serpentine shapes, the smallest of them looking like the letter S. The bacilli found in the urine, and also in pus taken from the kidney post mortem, presented exactly this appearance.

HERR A. BAGINSKY then exhibited some specimens demonstrating the

CHANGES INDUCED IN THE INTESTINAL CANAL OF CHILDREN BY CHRONIC CATARRH.

He had not seen any mention made of this condition in any of the recent text-books. The affection attacks first the mucous coat, but passing gradually into the deeper layers induces there changes of a very serious character. A child, seven months old, was brought to him for treatment, suffering for some time from diarrhœa and great emaciation. The stools were thin, mucous, and of a greenish color. After a period of temporary improvement the diarrhœa returned, and soon the child died. At the autopsy the mucous membrane of the large intestine was seen to be swollen and thickly studded with granulations, so that the intestine, when smoothed out, looked like a coarse file. On microscopical examination the glands of Lieberkühn were found to have undergone peculiar changes. They were of all sorts of odd shapes, presenting warty outgrowths and bifurcations, and on careful section the epithelium was seen to be the seat of hyaline degeneration. The speaker expressed the opinion that Lieberkühn's glands possessed a certain digestive function, and that the pathological changes occurring in them should be more carefully studied than they have hitherto been.

HERR BOECKER then related a case of

GANGRENOUS INFLAMMATION OF THE LARYNX,

situated in the aryteno-epiglottidean fold. Laryngeal examination showed large shreds of gangrenous tissue hanging down from the neighborhood of the pyramidal sinus. The patient stated that he had been suddenly seized, ten weeks before, with sore throat and difficulty in deglutition. At the same time there was considerable dyspnœa, and when this subsided the breath became so extremely offensive that he could not eat.

HERR ALTMANN then read an interesting paper on some of the

SUCCEDANEA OF DIGITALIS.

He had made a number of trials during the past year with caffeine and adonis vernalis in the treatment of cardiac and renal diseases, and thought that a recital of the results obtained by him would not be without interest. His experience with

CAFFEINE

had been that under its influence the heart's action was strengthened and the arterial tension increased. Its in-

fluence in reducing the frequency of the pulse was not as marked as that of digitalis. The urine was invariably increased in quantity during the administration of the drug. It had been stated by Riegel that the simultaneous exhibition of narcotics weakened the action of caffeine, and the author's experience had led him to the same conclusion.

ADONIS VERNALIS,

a wild plant of the order of ranunculaceæ, growing in southern Europe, was at one time employed as a drastic cathartic, and also as a heart-tonic, but had soon been forgotten. Some trials had of late been made of it by Dr. Bubnoff, at the instance of Professor Botkin, when it was found to possess some really valuable properties as a heart-tonic and diuretic. Cervello had found the active principle of the plant to reside in a glucoside to which he gave the name of

ADONIDINE.

Its action was very similar to that of digitaline in strengthening the cardiac pulsations, increasing arterial tension, and, after its continued administration for a length of time, increasing also the irritability of the striped muscular tissue.

The author had employed adonis in a number of cases of valvular disease, fatty degeneration, and myocarditis, as well as of parenchymatous nephritis. He gave in detail the history of two cases in which he had employed adonis with signal success after having been obliged to discontinue digitalis on account of the dangerous symptoms produced. Yet adonis did not act equally well in all cases. In two instances he was forced to give it up owing to its causing pain in the kidneys and general malaise. The simultaneous administration of narcotics in these cases had seemed to influence its action in no noticeable degree. All observers agreed that there was no cumulative action of the drug. That large doses might be given without danger was evidenced by the fact that the Russians were accustomed to take it in unlimited quantities as a remedy against the drinking habit. It was given medicinally in infusion or decoction (℥ j.–ij. to ℥ vj.), in doses of a tablespoonful four or more times a day. In conclusion, Herr Altmann submitted that adonis vernalis is a cardiac regulator in the same sense as is digitalis. It strengthens the heart's action and reduces the number of its pulsations, raising at the same time arterial tension, and increasing markedly diuresis. The indications for the use of adonis are the same as for digitalis, but it is more rapid in its action than the latter drug, and never exhibits any cumulative effect. Finally, it may often be productive of good results where digitalis has failed.

Herr Michaelis had had a case of excessive ascites and œdema which had resisted all the ordinary diuretics, and in which digitalis gave rise to most alarming symptoms. As a last resort he determined to try adonis, and was delighted to find that under its influence the excretion of urine was at once increased. The ascites and anasarca disappeared within a short time.

Herr W. Lublinski was induced to try adonis vernalis on the recommendation of Professor Botkin, of St. Petersburg. He had used it in a number of cases of dropsy consequent upon valvular insufficiency, cardiac debility, and Bright's disease. The principal effect of the drug, and that by which it won its fame in Russia, is seen in increased diuresis. He had observed one peculiarity in the diuresis of adonis, which was that the specific gravity remained high, although the total amount of urine excreted was so greatly increased. This was due to the fact, noticed by Botkin, that there was an increased excretion of urates and chlorides during the administration of the drug. The speaker had not observed the favorable influence upon the heart which others had claimed for adonis. In a few instances only had he seen any increase of strength in the heart's action, neither had the pulse become less rapid and more regular, nor the dyspnœa less urgent. In most cases he was obliged to fall back on digitalis in order to obtain this result.

In addition to this disadvantage, adonis possesses some very unpleasant, though not dangerous, properties. Herr Lublinski's patients had complained much of the extreme bitterness of the drug, and he had found nothing which would in any noticeable degree disguise this taste. It often caused nausea, and even vomiting, and sometimes had to be discontinued on account of a diarrhœa which was excited by it. In summing up the results of his experience, the speaker maintained that adonis vernalis could never be accepted as a substitute for digitalis in all cases. It is useful in those cases in which it is desirable to induce diuresis; but even here it should be given only when digitalis is contraindicated by the existence of a very slow pulse, or when a cumulative action is to be feared. He stated, for the benefit of those who might wish to try it in their practice, that it could be obtained of Gehe & Co., in Dresden.

The active principle, adonidine, is a glucoside, containing no toxic properties. It is amorphous, dissolving freely in alcohol, but only slightly soluble in water and ether. The maximum dose for a frog is 1¼ grain. It has no cumulative action.

Herr Lenhartz had used adonis in a number of cases of pleurisy, nephritis, weak heart, etc., in which all other remedies had failed. The results were in general very favorable. He was especially pleased with the diuretic action of the drug.

Herr Leyden stated that he was engaged in the attempt to make other more satisfactory preparations of adonis than those hitherto in use, but his labors had as yet been unproductive of result. The active principle was unsuited for internal administration, owing to its slight degree of solubility in water. Adonis had advantages as well as disadvantages in comparison with digitalis. It exerts no regulating action upon the heart, and seldom slows the pulse to any appreciable degree. Its chief advantage is that it has no cumulative effect, and further, it causes no such digestive disturbances as are frequently seen to follow the prolonged administration of digitalis. It can also be given in many cases of weakened heart and slow pulse in which digitalis would be contraindicated. It is, upon the whole, the best succedaneum of digitalis that we possess.

As regards

CONVALLARIA,

the speaker said that his early experience with the drug had not been of such a nature as to encourage him to continue in its use. Squills resembled adonis in its diuretic action, but it was less reliable. He thought the history of adonis exemplified very strikingly

THE RELATIONS BETWEEN PHYSIOLOGICAL EXPERIMENT AND MEDICAL PRACTICE.

There are many substances which possess properties similar to those of digitalis, and which give almost identical results in experiments upon frogs. But in practice it is found that the various drugs are by no means of equal value. Thus it is evident that in the treatment of pathological conditions we cannot rely wholly upon the properties of any drug as determined in the laboratory, but must determine anew for ourselves, by actual experiment, what value each substance possesses when brought face to face with disease.

The Society, on motion, then adjourned.

The Forceps in Breech Presentations.—Professor R. Harvey, of Calcutta, advocates the use of the forceps in breech presentations in certain cases (*Indian Medical Gazette*, June, 1884). In this opinion he is now supported by Huter, Haake, Lusk, Gooch, Hamilton, Miles, and Agnew, so that the older views as to the inutility of this procedure need to be somewhat changed.

THE BIOLOGICAL SOCIETY OF PARIS.

Stated Meeting, July 12, 1884.

M. Paul Bert, President, in the Chair.

(Special Report for The Medical Record.)

The Society was called to order by the President.

M. Mairet detailed the results of some experiments made by him to determine the modifications occurring in the

ELIMINATION OF PHOSPHORIC ACID

in the subjects of epilepsy, melancholia or mania In the latter disease the results differ according to the particular phase during which the investigations are made. In the stage of excitement there is an increase in the elimination of nitrogen and phosphoric acid. In the period of depression the nitrogen and alkaline phosphates are diminished, while the earthy phosphates are increased. There is a decrease in both nitrogen and phosphates during a remission. In epilepsy there is an increased elimination of these substances during an attack. In melancholia the earthy phosphates are increased in amount, and the alkaline phosphates and nitrogen are diminished. M. Mairet thought his investigations were of practical value as furnishing indications for the treatment of these affections.

M. Henninger described the method employed by him in determining the

PROPORTION OF NITROGEN IN UREA.

This method was a modification of that proposed by Dr. Kjedal, of Copenhagen. It was very simple, and could be completed within two hours.

M. Gréhant then called attention to the dangers of the

DISINFECTION OF BAGGAGE BY NITROUS VAPORS,

as was done in some of the railway stations. The porters who removed the disinfected baggage incurred no slight risk. Experiments upon dogs had shown that the respiration of nitrous vapors was always dangerous, and might even be fatal in its consequences. It was very well to try to kill the microbes, but it was hardly the correct thing to kill men at the same time.

M. Rabuteau thought that the question raised by M. Gréhant was one of very grave importance. The inhalation of nitrous vapor determines profound changes in the blood, the effects of which may not be seen immediately. Workmen exposed to these fumes had been known to die suddenly after they had returned to their homes, although while at work they had experienced no ill effects.

M. Henninger cited the case of a chemist in Edinburgh, who died in consequence of inhaling these vapors. His laboratory assistant was also made very ill, but finally recovered.

M. Gréhant read a note upon

ALIMENTATION BY PEPTONES,

and demonstrated a simple method of making peptones for therapeutic use.

M. Bouchereau had prescribed peptones in a number of cases of mental disease, and had observed a marked improvement in the physical condition, and sometimes also in the mental state.

M. Henninger mentioned a paper which he had published upon the

RECTAL ADMINISTRATION OF PEPTONES.

He also related an instance in which a patient, who had become greatly reduced, lived for several weeks upon injections of peptones. He always added sugar and laudanum to the enemata. He had never seen any inflammation of the rectum following these injections.

M. Quinquand had studied the effects of peptones in the direction of increased bodily weight and augmentation in the quantity of urea excreted. He had found an increased formation of urea to take place at the same time that the patient gained in weight. This he thought, proved conclusively that the peptones were assimilated. He related several cases in which he had observed benefit from this mode of alimentation.

M. Dastre thought that the facts related by M. Quinquand were especially valuable in disproving the statements made by certain German writers. These latter, having examined only the products of respiration, presumed to assert that peptones were inert.

The Society then adjourned.

THE HOSPITALS MEDICAL SOCIETY OF PARIS.

Stated Meeting, July 11, 1884.

M. Bucquoy, President, in the Chair.

(Special Report for The Medical Record.)

The Society having been called to order, M. Besnier delivered an address of some length upon the desirability of preparing for

THE APPROACHING CHOLERA EPIDEMIC.

He thought it necessary for the physicians of Paris to bestir themselves if they wished to avoid a repetition of what had just occurred at Marseilles. The daily papers were full of the visit made by Dr. Koch, in the character apparently of sanitary inspector and adviser to the physicians and municipality of that city. Now, either the physicians knew beforehand all that Dr. Koch told them, and his advice was therefore superfluous, or else they did not know it, and then it was not to Dr. Koch that they should have applied for instruction. M. Besnier then spoke of the measures that had been taken in Paris to prepare for the probable appearance of the disease. Two hospitals, of the capacity of two hundred beds each, had been made ready, one on each bank of the Seine. In the event of an epidemic, therefore, there was accommodation for four hundred patients at once, and then there would be time enough to prepare for more if occasion arose. He stated, in answer to a question of one of the members, that experiments were now being conducted to determine the practicability of

BURNING THE CHOLERAIC DISCHARGES.

This was to be done by means of portable furnaces mounted on wheels. The dejections could be thrown into the furnaces as soon as they were received. If this idea were practicable, it would certainly be an efficient way of destroying every contagious principle.

M. Vallin then read a very interesting paper upon the

TRANSMISSIBILITY OF PULMONARY PHTHISIS.

The paper was in reality the report of the committee on phthisiology appointed by the Society some time previously. The author first gave the facts upon which was based the doctrine of the inoculability of tuberculosis, and stated that the contagious principle was contained in the tubercular matter, the muscles, and perhaps also in the lymph and the milk. It had been admitted that the tubercular virus was inoculable, but at the same time it had been denied by some that it could be transported from one person to another in the ordinary conditions of every-day life. The author thought, however, that the evidence of the contagiousness of phthisis was certainly as convincing as that in the case of glanders, and there were very few who would care to deny the contagiousness of the latter disease One fact worthy of careful study in this connection was the danger of the formation of

CENTRES OF CONTAGION

in houses in which a number of phthisical patients had been collected together. Cohnheim, who had formerly denied the contagious nature of tuberculosis, was converted to the opposite opinion by the fact that his animals all became tuberculous, although they had not been

inoculated, simply from living in his laboratory, which had become infected with the tubercular virus.

It has been denied that the facts observed in animals were applicable to man, but the cases of contagion recorded by the Collective Investigation Committee in England are so numerous as to be virtually conclusive. Of the 1,078 answers received to their circular concerning the transmission of tuberculosis, 261 were affirmative. Of this number there were 190 cases in which phthisis occurred in those who had no hereditary predisposition. A similar result was obtained by the German committee. One case in this category was particularly striking. Dr. Hyades, a physician attached to the Cape Horn mission, stated that phthisis was unknown among the natives of Terra del Fuego before the advent of the English missionaries, and this despite the fact that they lived in the open air, but scantily clothed and exposed to all the vicissitudes of an intemperate climate. But after they had been partially civilized, although they were now warmly clad and lived in decent houses, they were nearly decimated by phthisis. Among the missionaries with whom they lived there were several with tuberculosis.

It had been asserted that those who became tuberculous after nursing phthisical patients, became so in consequence of the fatigue and anxiety from which they suffered. But if this were the case, those who nurse patients with cardiac, renal, or other chronic diseases ought equally to become consumptive, and this, experience shows, does not occur. It is true the negative testimony against the contagiousness of tuberculosis is very strong, but taken in connection with the positive testimony on the other side, it only proves that pulmonary consumption is not as markedly contagious as some other diseases, measles or small-pox for example.

Having thus established, M. Vallin continued, the contagious nature of the disease, he would now lay down some general rules bearing upon the

PROPHYLAXIS OF TUBERCULOSIS.

Physicians should be careful, while seeking to enforce the necessary prophylactic measures, not to preach too strongly the theory of contagion in phthisis. For the public was very selfish and quick to take alarm, and if once people became convinced that there was a real danger of contagion in this disease, they might run to the extreme, and shun the consumptive as they would a leper. A patient with phthisis should always sleep alone, in a well-ventilated room. Especial care should be taken in the case of patients with the buccal, pharyngeal, or laryngeal forms of tuberculosis, and it would be well for these to inhale iodoform vapor, in order to render their breath as innocuous as possible. Children convalescing from measles and bronchitis of the smaller tubes should be kept away from association with consumptives. Patients should be forbidden to expectorate in their handkerchiefs or on the ground, but should use spittoons containing some damp sand or sawdust. The spittoons should be washed in boiling water or in a solution of chloride of zinc, one ounce to twenty ounces of glycerine and water. The rooms in which phthisical patients have died should be disinfected by burning sulphur, one ounce to every cubic yard.

Finally M. Vallin summed up the

CONCLUSIONS OF THE COMMITTEE

briefly, as follows:

1. The transmissibility of pulmonary tuberculosis is very probable, though not as yet indubitably proven by facts.

2. Isolation of consumptives, in the same sense as that of patients suffering from diphtheria or small-pox, is neither necessary nor desirable. Yet in view of the probable contagiousness of the disease, the public should be urged to adopt certain prophylactic measures similar to those enunciated in the body of the report.

The Society then adjourned.

Correspondence.

THE PERIOD OF GREATEST RISK FROM CONSUMPTION.

To the Editor of The Medical Record.

SIR: In THE MEDICAL RECORD of July 12th there is an article by Edgar Holden, M.D., entitled "When are we at Greatest Risk from Consumption?" He writes as follows: "Rare facilities for prosecuting an investigation to obtain a correct result have led me with considerable labor to a conclusion as startling as I trust it will be found conclusive, viz., that death from consumption, instead of being, as is almost universally supposed, most prevalent in early adult life in this country is in reality not so, but grows relatively more frequent as life advances." He supports this position with suitable arguments, and a diagram showing by figures the actual and relative mortality from the disease at different periods of life. I do not object to, but concur in his conclusion, although it is not so novel and consequently so startling as he supposes, but I do object to his appropriating without definite acknowledgment the labors of others. The subject of the relation of age to consumption was carefully examined by myself for the Mutual Life Insurance Company from the statistics of their own experience and the best tables of vital statistics then accessible. The results were published by the company in 1877 in their "Mortuary Experience of the Mutual Life Insurance Company of New York." The diagram published by Dr. Holden is his own, but the statistics and figures on which it is founded are, with one exception, those published in the above-mentioned report and here used by him without acknowledgment. The one exception is the experience of the life insurance company with which he is connected. The statistics of this company are valuable, but they can scarcely be supposed to possess, like Aaron's serpent, a miraculous power of swallowing all the others.

Dr. Holden's words would seem to indicate that the "considerable labor" was his own, the line of argument his own, and the "startling conclusion" a discovery of his own, while at the very time of constructing his diagram he was using another's work, and had before him the pages elaborating the same line of argument and establishing by statistics a conclusion which had been known to Laennec, Watson, and Christison.

Respectfully yours,

E. J. MARSH, M.D.

PATERSON, N. J., July 21, 1884.

SHALL OFFICERS OF THE ARMY ENGAGE IN PRIVATE PRACTICE?

To the Editor of The Medical Record.

SIR: On July 19th you published in THE RECORD a letter from Dr. John G. Stanton, in which he complains of the privilege granted officers of the army to engage in private practice. The statements which the doctor makes are presented in such an *unfair* light that they should be answered. It cannot be done better than by giving an extract from a letter written by Dr. Heiskell many years ago, when he was in charge of the Surgeon-General's Office, more so since it seems that his opinions have been a guide in matters of the same nature ever since. Dr. Heiskell wrote as follows:

"Whether, by your expression, 'putting themselves in competition' with you, you mean to convey anything more than that they comply with the applications of those who desire their professional aid, is not clearly understood. If neither a breach of professional etiquette nor any improper means to obtain professional employment is charged against them, it is not perceived that this department can, with propriety, interfere in the matter. . . . When, therefore, it does not interfere

with their military duties, medical officers have a right to give their professional advice, etc., to whomsoever they please, and they have always been permitted to do so with a view to their professional advancement. Indeed, at military posts occupied by a small number of troops, and where of course the subjects of disease are few in number, and the complaints of these few present but little variety of character, it is rather desirable than otherwise that the army physician should extend his sphere of action to the citizens immediately around him, so as to become familiar with disease under all circumstances, the maladies prevailing through the country and among the citizens generally, as well as the diseases peculiar to the soldier, or to military life in camp or garrison. To deprive the army surgeon of any reasonable opportunity of practical advancement in his profession would surely be inflicting an injury upon the service generally, and especially upon those who have to depend upon him for professional aid. . . . It may not be out of place incidentally to state, that to prohibit a medical officer (when his public duties will permit) from extending relief to those of his fellow-citizens who may apply for his services—having confidence in his professional attainments—would be as ungracious to them as it would be devoid of the common dictates of humanity, and might afford as just and perhaps a better cause of complaint on the part of the neighboring community than the one alleged by yourselves, which relates exclusively to private interests. . . ."

Such was the language of an officer and a gentleman, addressed to some physicians at Sackett's Harbor, N. Y., and the high social and professional standing the officers of the medical corps of the army have always enjoyed will be sufficient proof that it is not their custom "to pirate outside of their posts."

The statement that there are too many surgeons for the number of troops is not supported by facts. It is true that at some stations the garrisons are small, but not every military post can be occupied by a large force. And even at such points it has been found much more satisfactory, for military reasons, to have the duties of post-surgeon performed by a regular medical officer or an acting assistant surgeon, than to employ a private physician, living in the vicinity, and pay him for each visit. Very respectfully, CADUCEUS.

ELECTROLYSIS IN STRICTURES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of THE MEDICAL RECORD for July 26th, I see an article upon "Electrolysis in Stricture," by Dr. Streeter, of Rochester, N. Y., which seems to me so arbitrary in its dictum regarding the successful treatment by the above process, and this dictum seems to be so entirely based on the doctor's own unsuccessful experience, that I cannot but attempt a reply.

Having been the assistant of Dr. Robert Newman for the last four years, both in dispensary and private practice, I have had ample opportunity of convincing myself that he (Dr. Newman) is successful with this method, whatever experience others may have. It is very commendable to report our failures, as thereby we may profit and arrive at the truth. The conclusions, however, and comments the doctor arrives at through his failures are opposed to both logic and facts; so that the paper gives the impression as if it were a partisan one and not simply in the interest of science. If Dr. Streeter does not succeed with electrolysis it does not follow, by any means, that therefore electrolysis is a failure, but the fault should be looked for in the operator, not in the instrument. If one single person succeeds by the method (and there are scores on record who have succeeded), a thousand may fail, and without its affecting the fact that it can be done, in the least.

All recent text-books have acknowledged the success of electrolytic treatment, and give their authorities. Many respectable practitioners of standing, all over the country, have reported their cases for the last fifteen years, so that now it would be easy to collect one thousand cases. At the meeting of the American Medical Association in Cleveland, O., in 1883, one hundred successful cases were reported, which *had been under observation for from four to eleven years without a relapse.* Under such circumstances it is very unkind of Dr. Streeter to say: "No recognized authorities upon surgery or electricity have reported, etc."

Next, it is unfair to resuscitate the ten old cases of Dr. K——, in 1871. It has been shown why these cases were not a success in THE MEDICAL RECORD of July 15, 1872, and other articles. Besides, the present method and present knowledge of the electrolytic process as applied to strictures should not be compared with the rudimentary experiments of 1871.

Dr. Streeter also says: "In no other similar affections—stricture of the œsophagus, rectum, etc., have such results been claimed for electrolysis." Far from the mark! They have been claimed, and are on record. Strictures of the rectum have been cured by electrolysis (*New England Medical Monthly*, September, 1882), and a specimen was presented to the New York Pathological Society on April 10, 1872, which proved not only the complete cure of the stricture, but also that not the slightest relapse had taken place, to which the most learned and critical audience present could not take exception.

Butler and others have cured stricture of the œsophagus beyond any doubt, and even strictures of the Eustachian tubes have been treated successfully by M. J. Mercié in the clinic of Dr. Désarènes (*Medical News*, quarterly epitome, March, 1883). The method of Dr. Goruki for nasal strictures, as also that for those of the lachrymal ducts, are on record.

As to the operation of cutting strictures for a cure, Dr. Streeter cannot *assert* that he cured them permanently, he is only able to say he *thinks* he cured them, which is a praiseworthy modesty.

The success of electrolysis in the cure of strictures is such an established fact now, and proven by so many successful cases on record, and many more joyful specimens of humanity who own a restored urethral calibre, that these few words are simply meant to correct some misleading statements made in the article of July 26th.

Yours truly,

G. C. H. MEIER, M.D.

NEW YORK CITY.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 3 to August 9, 1884.

GIBSON, J. R., Major and Surgeon. Granted leave of absence for one month and fifteen days. S. O. 36, Headquarters Division of the Atlantic, August 4, 1884.

HEIZMANN, C. L., Captain and Assistant Surgeon. Relieved from duty at Columbus Barracks, Ohio, and ordered for duty in Department of the East. S. O. 180, par. 2, A. G. O., August 2, 1884.

MCCREERY, GEORGE, First Lieutenant and Assistant Surgeon. Leave of absence extended two months. S. O. 180, par. 4, A. G. O., August 2, 1884.

HOPKINS, W. E., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence with permission to apply for one month's extension. S. O. 67, par. 1, Headquarters Department of Arizona, August 1, 1884.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 9, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
August 2, 1884	1	24	35	3	94	22	0	0
August 9, 1884	0	26	35	3	76	28	0	0
Deaths.								
August 2, 1884	1	6	7	3	19	14	0	0
August 9, 1884	0	7	7	3	20	12	0	0

CHLORAL-QUININE. — A compound of quinine with chloral hydrate has been made by Dr. Mazzara by adding the chloral to an equivalent quantity of quinine dissolved in chloroform. By evaporating the solution and redissolving the residue in ether, the new compound may be obtained in warty crystals, which are said to be volatile at 149° C. and to make fluorescent solutions with acids.—*Lancet.*

SUPERNUMERARY TESTICLES.—Dr. W. S. Cheesman, of Auburn, N. Y., writes: "I have been a little surprised to observe the credence which THE MEDICAL RECORD gives to accounts of supernumerary testicles. Not one of these cases has been established by convincing evidence. Mere manipulation proves nothing, and THE RECORD'S informers seem to have applied no other test. Well do I recall a case illustrating the liability of even the most learned and acute to self-deception in this matter. In December, 1879, an Irishman was admitted to Ward 6, Bellevue Hospital, who, besides having two aneurisms of his aorta, appeared to have two testicles on each side. The whole resident staff went wild with enthusiasm, and proudly invited some of the more distinguished of the visiting staff to examine the curiosity. One and two at a time they came in, handled the specimens, and went away convinced and awed. Now it happened that a certain surgeon, hearing of the case and the credulity of his *confrères* with amazement, demanded of one of them (a great pathologist and diagnostician) if he actually believed this Irishman to have *four testicles*. The other, reaffirming his belief, good-humoredly advised his interlocutor not to talk about the case till he had examined it; whereupon the critic asked to be led to where the marvel lay. There were present at this fiery trial most of the hospital staff, and, I think, certain of the visiting Board also. The inquisitor having carefully manipulated the scrotum and its interesting contents, inquired of each individual in turn his opinion thereupon. When all had committed themselves to the opinion that the man had four testicles, he called for a candle, and then and there demonstrated that two of the bodies in question were *encysted hydroceles* of the cord. To make assurance doubly sure, I introduced a hypodermic needle into each cyst and evacuated its serum, whereupon the plump, round, firm pseudo-testis collapsed. Since that afternoon my opinions as to superfluous testicles have conformed strictly to the teachings of scientific medical literature, to the exclusion of the sensational evidence of mere manipulation, whether practised by myself or by any one else. Authors dismiss this subject with the verdict, *Not proven.* It is, of course, difficult to understand why, when women are now and then accorded the most liberal and varied multiplication of their generative apparatus, and when men are occasionally vouchsafed that embarrassment of riches, a double penis, there should not also occur undoubted cases of supernumerary testicle. Yet such is not the fact. All pretended abnormalities of the sort have, when submitted to rigid criticism, turned out to be cystic or fatty tumors, or what-not. Will not some one come forward with a dissected specimen (nothing less will carry conviction) of a scrotum containing three or more testes, and enroll his name beside that of the discoverer of a supernumerary moon?"

Dr. G. M. Burdett, of Lenoirs, Tenn., also writes: "An acquaintance of mine from Georgia has three testicles, but judging from his family none of them were supernumerary, according to Mr. Webster's definition of the word."

NOTES REGARDING THE PRESCRIPTION OF CORROSIVE SUBLIMATE.—Dr. G. G. Davis, of Trewsbury, N. Y., writes: "Corrosive sublimate, mercuric chloride, perchloride of mercury, the latest and best antiseptic, seems to be but little understood by the profession in general. Chemically, it is represented by $HgCl_2$, one mercury, and two chlorine. One atom of the latter element, not being entirely saturated by the Hg, tends to divorce itself and become free, to which fact the drug owes its potency. Great care should be taken in making it up into solutions, that the water should be filtered and distilled, or rain or snow water used in aqueous mixtures, or pure glycerine. These two articles are the best vehicles, and most convenient, and should always contain a little of some chloride, as common salt, hydrochloric acid, or chloride of ammonium, to keep the saturation continuous. I am aware that physicians prescribe this drug in alterative mixtures, tonics or syrups with vegetable extracts and such trash, which render the remedy perfectly inert. In fact, I know of but two very simple tinctures in which it may be prescribed and hold its virtues, viz.: gentian and cardamom. With tr. ferri chlor. and liq. acidi arseniosi of the new Pharmacopœia it forms a model remedy for pernicious anæmia. This is also a scientific mixture which will not decompose, and is a fair sample of a prescription for its internal administration. I would again call the attention of the profession to the avoidance of all *organic* materials in a mixture containing corrosive sublimate."

A CASE OF INTESTINAL OBSTRUCTION FROM TWISTING OF GUT—AUTOPSY.—Dr. P. T. Shillock, of Chaska, Minn., sends the history of a case of intestinal obstruction presenting several interesting points. The patient was a single woman aged twenty-eight, previously healthy, who had suffered for several days from colic and vomiting. She had taken several cathartic pills which acted sharply. Griping pains and vomiting continued, however, and she finally sent for the physician. Dr. Shillock found her suffering from abdominal pains and tenderness, tympanitis, and vomiting. Pulse, 106. Symptoms of obstruction gradually became more and more marked, and in three days she died from exhaustion. The use of morphine, anti-emetics, stimulants, cathartics, and enemata only gave temporary relief. Dr. Shillock writes: "On autopsy we found the obstruction to be caused by a double looping or twisting of the ileum, just a short distance from the ileo-cæcal valve. The stomach, small and large intestines were all much distended with gas. The large intestines were also quite congested, while the small intestines appeared normal, except at the point where twisting took place, being there of a dark red color. No evidence of peritonitis was present, and all the other viscera appeared to be normal. Points of interest in this case that seem to make it worthy of being reported were as follows: 1, The vomited material had only a very slight fecal odor on the last two days of the case; 2, apparent slight causation for such a serious condition; 3, setting in of menstruation only two days before her death; 4, equal distention of intestines both above and below obstruction, and passage of flatus during latter part of case."

THE NATURAL PRODUCTION OF MALARIA, AND THE MEANS OF MAKING MALARIAL COUNTRIES HEALTHIER.

AN ADDRESS DELIVERED AT THE EIGHTH SESSION OF THE INTERNATIONAL MEDICAL CONGRESS, COPENHAGEN, AUGUST 12, 1884.

BY CONRAD TOMMASI CRUDELI, M.D.,

PROFESSOR OF HYGIENE, UNIVERSITY OF ROME, ITALY.

(Special for THE MEDICAL RECORD.)

GENTLEMEN: Before entering upon my subject I must crave the indulgence of those of my colleagues whose language I have borrowed for any Italicisms that I may use, as well as for the foreign accent which must strike their ears more or less disagreeably. Desiring to respond as well as lay in my power to the invitation with which I have been honored to discuss the hygienic questions relating to malaria, I have chosen the French language as being the one in which, apart from my mother tongue, I could express myself with the greatest ease and precision.

I shall be pardoned also, I hope, for having employed the terms "malaria" and "malarial districts" in place of the more commonly used expressions "paludal miasm" (*miasme paludéen*) and "marshy regions" (*contrées marécageuses*). The substitution is not a happy one from a literary point of view, but I have made it deliberately and for the following reason: The idea that intermittent and pernicious fevers are engendered by putrid emanations from swamps and marshes is one of those semi-scientific assumptions which have contributed most to lead astray the investigations of scientists and the work of public administrations. This idea, so widespread and so well established by the traditions of the school, is radically false. The specific ferment which engenders those fevers by its accumulation in the atmosphere which we breathe is not exclusively of paludal origin, and still less is it a product of putrefaction. Indeed, in every region of the globe between the two arctic circles there are swamps and marshes, steeping-tanks of hemp and flax, large deltas where salt and fresh waters mix, and yet there is no malaria there, although putrid decomposition is on every side. On the other hand, in the same parts of the globe there are places which are not, and never were marshy, and in which there is not the least trace of putrefaction, but which, nevertheless, produce malaria in abundance. I reject, therefore, wholly the paludal assumption, and in order to express this view in the title of my paper, have been forced to employ terms which to my hearers may sound like Italicisms.

The Italians generally have not this paludal notion, for experience taught them long ago that malaria is produced nearly everywhere; in marshy districts as well as in those which might almost be called arid; in a volcanic soil as well as in the deposits of the miocene and pliocene periods and the ancient and modern alluvia; in a soil rich in organic matters as well as in one containing almost none; in the plains as well as on the hills or mountains. The word malaria (bad air), which it is the sad privilege of Italy to have lent to all languages to express the cause of intermittent and pernicious fevers, represents then, among the majority of our rural populations, the idea of an agent which may infect any sort of country, whatever may be its hydraulic and topographical conditions and whatever may be its geological formation. This word, therefore, is the one best suited to designate this specific ferment in question, and I have on this account employed it and its adjectival derivatives in order not to resuscitate the idea of the exclusively paludal origin of the morbific agent.

I shall not tarry long to speak of the nature of this ferment, for the studies bearing upon that point, although far advanced, are not yet completed. I may remark, however, that the idea that the ferment is formed of living organisms is a very old one, and has not arisen suddenly because of the modern theories of the parasitic nature of disease. From the time of Varrar (who believed that malaria was made up of invisible mites suspended in the atmosphere) to our own day this theory has been several times advanced by hygienists. Independently of the general considerations which led Rasori, and later Henle, to formulate the doctrine of the *contagium vivum* of infection (long before the progress of microscopical science had revealed the existence of living ferments), there were peculiar circumstances as regards malaria which should have impelled minds to look in that direction, even in times long past.

Some of these circumstances are of a nature to strike every serious observer, and deserve a few moments' attention. How could one maintain, for example, that this ferment is a product of chemical reactions taking place in the ground, when it is seen to remain constantly the same whatever may be the composition of the soil from which it emanates! As long as the paludal theory held sway the chemical interpretation of this identity of the product in every latitude was easy. Rica does not hesitate to admit that when a swampy tract is heated by the sun's rays to the necessary point for the putrid decomposition of the organic matters contained in it, the "chemical ferment," or rather the "mephitic gases," to which is attributed the morbific action, are developed, whatever may be the distance from the equator at which this marshy region lies. But since it has been ascertained that malaria is produced in soils of the most varied chemical composition, *the persistent identity of this product* has become chemically inexplicable; while it is however readily conceivable, if one admits that malaria is an organized ferment which easily finds the necessary conditions for its life and multiplication in the most varied soils, as is the case with millions of other organisms vastly superior to the rudimentary vegetables which constitute the living ferments.

The same thing may be said of *the progressive intensity of the morbific production in abandoned malarious districts.* This fact has been historically proven in several parts of the earth, and especially in Italy. A large number of Grecian, Etruscan, and Latin cities, even Rome itself, sprang up in malarious territories and attained a high state of prosperity. First among the reasons for this success must be placed the works undertaken with a view of rendering these places more salubrious, and which lessened the evil production, *but almost never extinguished it completely.* After the abandonment of these localities, the production of malaria recommenced in a degree which went on increasing from age to age, and which has rendered some of these places actually uninhabitable. This was seen, in the time of the ancient Romans, in Etruria, when it was conquered and laid

waste, and in several parts of Magna Græcia, and of Sicily. From the fall of Rome even to the present day, this phenomenon has been manifested in a very evident manner in the Roman Campagna, in certain parts of which, even up to the time of the Renaissance, it was possible to maintain pleasure houses, but which are now uninhabitable during the hot season. In many cases the physical conditions of the soil have undergone no appreciable change during centuries, so that it is impossible to attribute so enormous an augmentation of malaria to an increase in its annual production, itself increased by a progressive alteration of the chemical composition of the soil. But if, on the contrary, it be admitted that malaria is caused by a living organism whose successive generations accumulate in the soil, the interpretation of this fact becomes very simple.

There are, finally, *peculiarities in the local charging of the atmosphere with malaria* which can be explained only in this manner. If the malarial miasm were composed of gaseous bodies emanating from the soil, or rather of chemical ferments formed beneath the ground and raised into the air by gases or watery vapor, the charging of the atmosphere with the specific poison ought to arrive at its maximum during the hottest part of the day, when the ground is heated the most by the sun's rays and when the evaporation of water and all chemical actions attain their maximum intensity. But this is very different from what actually occurs. The local charging of the atmosphere is always less strong during the meridian hours than at the beginning and the end of the day, that is to say, after the rising, and especially after the setting, of the sun. Now it is precisely at these hours that the difference between the temperature of the lower layers of the atmosphere and that of the surface of the ground is the greatest, and that the ascending currents of air starting from the ground are the strongest. If malaria consists of solid particles contained in the soil, one may readily understand how their elevation *en masse* into the atmosphere should take place especially at these two periods of the day.

All these facts, which can be easily verified if the subject of malaria be studied on the spot and without any preconceived notions, explain the tendency which has always been manifested to attribute this specific poisoning of the air to a living organism which is multiplied in the soil; and they also explain the ardor with which hygienists have applied themselves to the production of the scientific proof.

Unfortunately the investigations undertaken for this end have for a long time been fruitless, for the preconceived paludal theory has led investigators to occupy themselves exclusively with the inferior organisms inhabiting marshes. Among these organisms they studied especially the *hyphomycetes*, which had already acquired so great an importance in dermatology; and their entire attention was concentrated upon the aquatic algæ, without even taking the precaution to determine whether the varieties which they thought to be malarial were found in all malarious swamps, or whether they were capable of living within the human organism. It has thus happened that each observer has indicated as the cause of malaria a different variety of alga, whichever he found to be most abundant in the swampy ground that he had to examine. Thus Salisbury has indicated the *palmella gemiasma*, which is found with us in places perfectly free from malaria, while it is often wanting in malarious marshes in the centre of Italy; Balestra, a species of alga which is as yet indeterminate; Bargellini, the *palmoglœa micrococca;* Safford and Bartlett, the *hydrogastrum granulatum;* and Archer, the *chitonoblastus œruginosus*. There is not a single one of these species the parasitic nature of which has been demonstrated; and as regards the two last named varieties, it can be positively denied that they are capable of producing a general infection, for the diameter of their spores and filaments is greater than that of the capillary blood-vessels.

It was only in 1879 that Klebs and myself, after having been thoroughly freed, by a long series of preparatory studies, from the unfortunate paludal idea, undertook together some investigations in malarious districts of the most varied character, marshy and not marshy. We employed the system of fractional cultivation, making experiments on animals with the final products thus obtained. We felt ourselves justified in recognizing the malarial ferment in the *schizomycete bacillus*. The numerous researches made subsequently by us, and by many other observers, in the soil and in the air of several malarious localities, as well as in the blood and in the organs of men and animals specifically infected, have put it henceforth almost beyond doubt that we really have to do with a schizomycete. Very recently, MM. Marchia fava and Celli have succeeded in demonstrating that the germs of this schizomycete attack directly the red blood-globules, and destroy them, causing them to undergo a series of very characteristic changes which admit of easy verification, and which render certain the existence of a malarial infection.

Several observations made recently in Rome tend to demonstrate that the schizomycete of malaria does not always assume the complete bacillary form described by Klebs and myself; but this morphological question possesses no further interest for the hygienist. For him the essential thing is to know that he has to deal with a living ferment which can flourish in soils of very varied composition, and without the presence of which neither marshes nor stagnant pools of water are capable of producing malaria.

We must not think, however, that all earth containing this ferment is capable of poisoning the superjacent atmosphere. Popular experience, certain modern scientific investigation, and the facts which one can often verify when the soil, which was malarious in ancient times and which has since ceased to be so, is turned up to a great depth, all agree in proving that the ground remains inoffensive as long as it is not placed in certain conditions indispensable for the multiplication of this specific ferment. Up to this point the organism lives, so to speak, in an inert state, and may remain so during centuries without losing any of its deleterious power. There is nothing in this fact that ought to surprise us, since we know that the life and the power of evolution belonging to the seeds of plants of a much higher order than these vegetable organisms constituting ferments, may remain latent for centuries, and may then revive at once when these grains are placed in the conditions suitable for their germination.

Among the conditions favorable to the multiplication of the malarial ferment contained in the soil, and to its dispersion through the superjacent atmosphere, there are three which are absolutely essential, and the concurrence of which is indispensable for the production of bad air (malaria). First, a temperature which does not fall below 20° C. (67.5° F.); next, a very moderate degree of permanent humidity of the soil; and finally, the direct action of the oxygen of the air upon the strata of earth which contain the ferment. If a single one of these three conditions be wanting, the development of malaria becomes impossible. This is a point of prime importance in the natural history of malaria, and it gives us the key to most of the methods of sanitary improvement attempted by man.

Let us see first what can be done in this direction without the labor of man. For nature herself makes localities salubrious by *suspending* for a greater or less time the production of malaria. It is thus that winter brings about in every country a freedom from malaria which is *purely thermic*, for it is due simply and entirely to a sinking of the temperature below the required minimum. Indeed, if the temperature in winter rises above this minimum, there are often sudden outbreaks of malaria. Sometimes, during very warm and dry summers, the heat extracts all the humidity from the malarious soil, and thus procures for us a freedom from the disease,

which is *purely hydraulic*. This may continue for a long time (as happened in the Roman Campagna during the years 1881 and 1882), but may also be completely destroyed by a single shower. Nature also sometimes renders a district healthy in a manner *purely atmospheric*, by covering a malarious soil with earth which does not contain the malarial ferment, or with a matting formed of earth and the roots of grasses growing closely together in a natural meadow.

In the attempts of purification by suspending the malarial action, which have been devised by man, the same thing has been done; that is to say, it has been sought to eliminate at least one of the three conditions essential to the development of the specific ferment contained in the infected soil. Naturally, they have not thought of bringing about a thermic purification, such as nature produces in winter, because of the impossibility of moderating the action of the sun; but they have tried from all time to procure hydraulic or atmospheric purifications, and sometimes to combine these together in a very happy way.

The hydraulic systems are very numerous, for the problem which is presented, namely, that of depriving the ground of its humidity during the hot season, necessitates different solutions according to the nature and the bearing of the soil. Sometimes this is done by digging open or closing ditches intended to draw away large bodies of water. At other times a system of drainage is established, by means of which the water is drawn out of the earth and its level is depressed, so that the upper malarious strata, exposed to the direct action of the air, are deprived of moisture during the hot season. This system of drainage is not a modern invention; the Italian monks understood it as well as, and even better than, we do. In deep and loose soils they used sometimes, just as we do now, porous clay pipes; but when the subsoil was formed of compact and nearly impermeable matters, they employed a system of drainage, the extent and grandeur of which astonishes us. It is that of drainage by cavities, applied by the Etruscans, Latins, and Volsci to all the Roman hills formed of volcanic tufa, the tradition of which I have found still preserved in some countries of the Abruzzi.

We may sometimes establish a double drainage, from below and from above; that is to say, to drain the subsoil, and at the same time increase the evaporation of water from the surface of the ground. It is well known that clearing off the forests of malarious countries has often proved an excellent means of making lands salubrious which were before too damp; for, by removing every obstacle to the direct action of the sun's rays upon the ground, we cause an increase of evaporation from its surface, and may thus be enabled to exhaust the superficial strata completely of their water during the hot season. In very moist lands which lend themselves readily to deep drainage, the combination of the latter with a clearing of the surface has, in almost every quarter of the globe, rendered possible a very widespread and sometimes quite lasting freedom from malaria. But, although a nearly universal experience proclaims this fact, there is a school which, following in the footsteps of Lancisi, maintains the contrary opinion, that it is necessary to preserve the forests in malarious districts, and even to increase their extent, since the trees filter the infected atmosphere and arrest the malaria in their foliage. This strange theory was formulated by Lancisi in 1714, on the occasion of the proposed clearing of a forest belonging to the Caetani family, and lying between the Pontine Marshes and the district of Cistema. Lancisi was completely imbued with the paludal notion, and consequently believed that the very severe malaria of Cistema was brought by the winds from the coast marshes, instead of being produced in the soil surrounding the district, which was then covered by this forest. He believed then that the forest acted as a protective rampart, and he prevented its being cut down. But toward the middle of the present century the Caetani had the woods cleared off from the entire belt of land surrounding Cistema. Twenty years later I was able to show that Cistema had gained greatly in salubrity. I published my observation in 1879, and, naturally, was taken to task rather sharply in the name of the sacred tradition. Happily these recriminations led our Minister of Agriculture to have the question studied by a special commission. This commission, after a conscientious examination extending over three years, of all the malarious localities in the province of Rome, has just published its report,[1] the conclusions of which are entirely in accord with the facts of universal experience. They were not able to verify a single fact in support of Lancisi's theory, while they found many of the same nature as that of Cistema, and which have resulted in overturning the theory entirely.

It has also been thought possible to practise drainage from above by means of plantations of certain trees which would draw considerable moisture from the earth, a method which might really be serviceable in some malarious districts. But in accordance with the idea that malaria is a product of paludal decomposition, the trees selected have almost always been the *eucalyptus*. It has been maintained that trees of so rapid a growth ought to drain the soil very actively, and also that the aroma of their foliage ought to destroy the miasmatic emanations. I have hitherto been unable to verify a single instance of the destruction of malaria by eucalypytus plantations, but I do not consider myself justified in denying the facts which have been stated by others. There is nothing to oppose the admission that these plantations, when properly made, may sometimes have been of great utility. I maintain frankly, however, that they have not always been so, and that it is necessary to guard against the exaggerations into which some have allowed themselves to fall in recent times. Such exaggerations might have been avoided if, instead of talking about these plantations on the basis of a theoretical assumption, the results only had been studied in places where the eucalyptus abounds. It would then have been known that even in the southern hemisphere, the original home of the eucalyptus, there are eucalyptus forests which are very malarious. This fact has been demonstrated by Mr. Liversige, professor in the University of Sydney, Australia. Among us also, although everybody was convinced by the statements of the press that the locality of the Tre Fontane, near Rome, had been freed from malaria by means of the eucalyptus, people were disagreeably surprised by an outbreak of very grave fever occurring throughout the whole of this colony in 1882, a year in which all the rest of the Roman Campagna enjoyed an exceptional salubrity. If, alongside of these hygienic uncertainties, we place the agricultural uncertainties, we must conclude that it is necessary to contend strongly against this fanatical prejudice in favor of the eucalyptus-tree. These plants are, in fact, very capricious in their growth. In full vegetation during the winter in our climate, they are often killed instantly by a sharp winter frost, by damp cold, by the frosts of spring, or by other causes which the botanists have not yet been able to determine. At other times, if the winters are very mild, these plants grow too rapidly in height and then are broken short off by moderately strong winds. It should further be mentioned that these plantations are sometimes very expensive. In fact, if the earth contains too much water it must be drained under penalty of seeing the roots of the eucalyptus rot. Then again, if the subsoil is compact, it is necessary to dig deep trenches in order to give room to the long roots of these trees, and often indeed these trenches must also be drained, as is done for olive-trees. The conclusion evidently is that it is better to confine ourselves to hydraulic methods of promoting the healthfulness of a locality, the immediate effects of which are

[1] Della influenza dei boshi sulla malaria dominante nella regiona marittima della provincia di Roma. Annali di Agricoltura, No. 77, 1884. Roma: Eredi Botta.

less uncertain. And then, when the local conditions are such as to make it desirable to try the effects of plants possessed of strongly absorbing powers, it is better to choose them from among the flora of our own hemisphere. This is more sure and will cost less.

Simple hydraulic methods of purification, even the most perfect, do not, however, produce permanent hygienic effects, since the moisture necessary for the multiplication of the malaria in the soil is so slight that these effects may be compromised by anything whatever that is capable of restoring a moderate degree of humidity to the ground during the hot season. It has often been thought that a suspension of malarial production would be better assured by suppressing at the same time the humidity of the soil and the direct action of the oxygen of the air upon the superficial strata of earth which contain the ferment. This has been successfully accomplished by the system of overlaying (*comblées*). This consists in covering the infected soil by thick layers of uninfected earth, carried there either by the muddy waters of rivers or by the hand of man. At the same time the steady drainage of the surface and underground water is provided for. Last year, I advised our Minister of War to undertake in another form an hydraulico-atmospheric purification of the district of the Janiculum surrounding the Salviati palace on the via della Longara, by draining the soil carefully and covering with a layer of very close turf all the parts of the surface which could not be macadamized. It would seem as if this system had been rather successful, since there has not been this year a single case of fever in the *personnel* of the new military college, established in the Salviati palace ; while in the Corsini palace, which is situated on the same side of the via della Longara, but which looks out upon that part of the Janiculum which is still uncovered, there have been some fatal cases of fever.

Furthermore, we have had in Rome, during the past few years, some very evident proofs of the efficacy of atmospheric methods of purification. I will confine myself to the relation here only of the most striking instance, one which has been furnished us in the building up of new quarters of the city. There was much discussion at first as to whether the improvements should be undertaken in the parts where they now are or in the valley of the Tiber, for the uncovered lands of the Esquiline and of the Quirinal were malarious, and, as nearly everybody then thought that the malaria of Rome was carried into the city from the coast marshes, it was supposed that this state of things was irremediable. We opposed to this view the fact of the salubrity of the Viminal, which is situated between the Esquiline and the Quirinal, and which ought to be as unhealthy as the two other hills were the malaria of the latter imported into the city instead of being indigenous. Believing it to be indigenous, we hoped that by shielding the surface of these hills from the direct action of the air (by building houses and paving the streets), the malaria would cease to be produced there. That is precisely what has happened, for the new quarters are very healthy. But the malaria is only held in abeyance and is not definitely overcome ; for if an extensive excavation is made in these hills, and the contact of the air with the malarious soil is thus re-established, during a hot and damp season, the production of malaria commences anew. A complete atmospheric purification is nevertheless the most stable of all the methods of obtaining a suspension of malarial production, but unfortunately its realization is very limited, for it is restricted to inhabited localities and to sodded surfaces.

The ideal method of insuring freedom from malaria should be to obtain a permanent immunity, that is, to be able to modify the composition of the infected soil in such a way as to make it sterile as regards malaria, without taking from it the power of furnishing products useful for the social economy. But all the elements indispensable for obtaining such a result fail us utterly just here. We do not yet know what ought to be, in general terms, the composition of a soil incapable of producing malaria, yet retaining those properties which are suitable for vegetation. When we shall have arrived at this first stage, there will still be a long road to travel ; and the most difficult part will be to discover a practical means of imparting this salutary composition to all the numerous varieties of malarious soils.

Scientifically, then, in the present state of our knowledge, we are unable to affirm anything on this point. Practically, we are not much further advanced. It is very probable that the combination of hydraulic purification with a forced cultivation of the soil has sometimes determined changes in its composition by which it has been rendered sterile as regards malaria. If that has happened, it has happened by chance, and we are unable to reproduce the result at will ; for we have not all the data which might enable us to understand how it has come about. Most of the purifications obtained in ancient times, by means of forced cultivation, continued during centuries, have not been definite at all, but the production of malaria has been simply suspended. Hardly was the regular cultivation of the fields interrupted than the production of malaria recommenced. Among the numerous examples that I might cite in this connection, I will limit myself to that of the Roman Campagna. This seemed to have been made permanently healthy under the Antonii, but after the fall of the empire it began again to produce malaria, as if the forced cultivation through so many centuries had never been.

One might, strictly speaking, be content with such a result, and boldly undertake forced cultivation of all malarious districts, without stopping to ascertain whether the freedom from malaria so obtained would be definite, or whether the production of the poison were only suspended. Unfortunately one is never sure of arriving at such a result, and no one can say *à priori* whether the forced cultivation of a given malarious tract will render it healthful. It must always be remembered that the first effect of forced cultivation, which requires an overturning of the soil by means of the plough, the spade, and the pick, is an unfortunate one, from a hygienic point of view, whenever we have to deal with a malarious country. Experience has shown, especially in Italy and America, that this overturning of the soil almost invariably increases the local production of malaria. And this can be readily understood, since the ploughing and the digging in a soil containing the specific ferment increases the extent of surface of the ground in immediate contact with the atmosphere. This first mischievous effect is often gradually weakened by the continued cultivation, and may end by disappearing. At other times, on the contrary, it persists obstinately, and one is often forced in desperation to the resolve to level the ground again and to varnish it, so to speak, with a thick sowing of grass, if he wishes to suspend or weaken the malarial production.

However, when the local conditions will permit, it is well to try whether, by means of forced cultivation of the soil, it may not be possible to increase the efficacy of the hydraulic method of procuring immunity from malaria, or of the hydraulico-atmospheric method of "overlaying." The moment that it is known that this cultivation has frequently been advantageous, there comes forward a crowd of social reasons which induce us to attempt it, even though we be persuaded that we are about to engage in a game of chance. But to dare to attempt it is not all that is necessary, we need also the possibility of so doing, and just here we find ourselves in a vicious circle from which it is not easy to emerge. Forced cultivation cannot be accomplished without the presence of agriculturists in the region during the entire year ; and the agriculturists cannot remain in the region during the fever season, for they run thereby too great a risk. For the solution of this question there is but one means : *try to increase the power of resistance of the*

human organism to the attacks of the malaria. It is to a search after the means of accomplishing this result that I have devoted myself during the past few years.

There is nothing to hope for, as regards malaria, in acclimation. *Individual acclimation* is, and always has been, impossible. The malarial infection is not one of those a first attack of which confers immunity from other attacks. It is, on the contrary, a progressive infection, the duration of which is indeterminate, and which is of such a nature that a single attack may suffice to ruin the constitution for life. Collective or *racial acclimation* certainly existed in the past, at a time when specific remedies for pernicious malaria were unknown; and even later, when the employment of these remedies was very limited. The acclimation was due to a natural selection made by the malaria upon successive generations, from which it took away, almost without opposition, all those who possessed but a feeble individual power of resistance to the specific poison, while it spared those who possessed this power of resistance in an extraordinary degree. The first were, according to the Grecian myth, *the human victims destined to appease the monster, or demon, who opposed the violation of the territory over which he had up to that time exercised an absolute sovereignty.* The second became the founders of the race, and through them, from generation to generation, the collective power of resistance to the malaria was progressively increased. In our own days a like selection may take place among barbarous races, as it does among the cattle and the horses in a malarious region, but it has become an impossibility among civilized nations. By means of the specific remedies which we possess, the use of which is now so general, the lives of a large number of individuals whose resisting powers are very feeble are preserved; and these individuals beget others whose power of resistance to the action of the specific poison is still more feeble. This results, after a number of generations, in the physical degradation of that part of the human race which inhabits malarious countries.

We cannot, therefore, in the future, count upon the assistance of external natural forces to increase the power of resistance of human society against the assaults of malaria. Such an object can be obtained only by artificial means. It has been sought to attain this end by the daily administration of the salts of quinine, of the salicylates, and of the tincture of eucalyptus, each and every one tried in turn. But the salts of quinine are dear, exercise a prompt, though very transient, anti-malarial action, and, when administered for a long time, disturb rather seriously the functions of the digestive and nervous systems. The salicylates, when well prepared, are rather dear, and there is as yet no proof that they possess prophylactic powers against malaria. The alcoholic tincture of eucalyptus is useful in malarious regions (as are all the alcoholics, beginning with wine) in quickening the circulation of the blood; may it, perhaps, also act as a preservative against light attacks of malaria? Possibly. But it is very certain that it possesses no efficacy in places where malaria is severe. It will suffice to prove this to recall the two epidemics of fever which afflicted the colony of the Tre Fontane, near Rome, in 1880 and 1882. Everybody was attacked, and there were several cases of pernicious fever, although a good preparation of eucalyptus is manufactured in the place and is distributed largely to the colonists during the dangerous season of the year.

Having several times had occasion to observe, in malarious regions, that when recourse was had to arsenic in order to subdue fevers, over which quinine had exerted almost no effect, relapses occurred but rarely; and having been able to satisfy myself that the arsenical treatment sometimes procured a permanent immunity in individuals who are subject to frequent attacks of malaria, I began in 1880 to employ arsenic (arsenious acid) as a prophylactic in certain portions of the Roman Campagna. This remedy was indicated, in an experiment of this sort, not only by reason of its durable anti-malarial effects, but also by its low price, by the beneficial influence which it exerts upon all the nutritive functions, and because it has no disagreeable taste and may therefore be given to everybody, even to children. My first trials in 1880 were rather encouraging, and I felt myself justified in engaging some proprietors and the association of our southern railroads to repeat the experiments on a large scale the following year, recommending them, however, to use arsenic in a solid form as offering an easy and certain dosage. This extensive prophylactic experiment began in 1881, and acquired constantly increasing proportions in 1882 and 1883, which have become still larger this year. An experiment of this kind is not easy to conduct in the beginning. The name, arsenic, frightens not only those whom we desire to submit to its action, but also the physicians, whose exaggerated fears have sometimes rendered the experiments of no avail, since they were conducted too timidly and the doses of arsenic employed were altogether insufficient. But some intelligent men, especially M. Ricchi, physician-in-chief to the southern railroads, were able speedily to triumph over these obstacles, and to place the experiment on a firm basis. The general testimony of all the facts which they have collected tends really to prove that, when the administration of arsenic is begun some weeks before the presumed season for the appearance of the fever, and when it is continued regularly throughout the whole of this season, the power of resistance of the human organism to malaria is increased. Many individuals gained thereby a complete immunity, others a partial immunity, that is to say, they were sometimes attacked by the fever, but it never, even in very malarious districts, assumed a pernicious form, and was easily subdued by very moderate doses of quinine. Last year, for example, in the district of Borino, where the malaria is very severe, M. Ricchi experimented upon seventy-eight employees of the southern railroads, dividing them into two equal divisions, one of which received no prophylactic treatment, while the other was submitted to a systematic arsenical treatment. At the end of the fever season it was found that several employees among the first half had been attacked by fevers of a severe type; while thirty-six of those in the second division had enjoyed a complete immunity, the three others having been attacked, but so lightly that they cured themselves by quinine without seeking medical aid.

Facts of this sort are very encouraging, and the more so as the general health of those submitted to the prophylactic treatment was much improved. It was found almost invariably, upon the termination of the experiment, that there had been an increase in bodily weight and an amelioration of the anæmia which is so common in malarious districts. But, in order to arrive at such results, it is necessary to be at once bold and prudent. On the one hand, it is necessary to graduate very carefully the daily dose, never exceeding at the commencement the dose of two milligrammes ($\frac{3}{10}$ grain) per diem for adults, and never giving the arsenic upon an empty stomach. On the other hand, it is necessary to gradually push the dose up to ten or twelve milligrammes ($\frac{15}{100}$ or $\frac{18}{100}$ grain) a day for adults, in districts where the malaria is very severe, giving the arsenic in such a way that there is never an accumulation of the drug in the stomach. Most of the experiments which have been undertaken this year are being conducted on this plan, and there is reason to hope that they will give satisfactory results.

We must not, however, rest here if we wish to attain promptly the end proposed, namely, that of planting colonies in malarious districts without exposing the colonists to grave danger. Even if we realize perfectly the hope which I conceived in 1880, and if we are enabled to prove that arsenic increases man's power of resistance to the assaults of malaria, we must not imagine that everything is accomplished. It will take a long time before the use of a preservative method of this kind becomes

generalized, we have first to contend against the fear which nearly every one experiences when arsenic is mentioned, and then there will also be difficulty in establishing everywhere a proper control over its administration. In every attempt at the colonization of malarious regions it will be necessary to combat for a long time the diseases caused by malaria, and we must seek for a method of combating them by a means which is in the possession of everybody, and which shall not be dangerous to the general economy of the human organism. Those who do not know from actual experience the miseries of a malarious country, think only of combating the acute forms of infection, which often place the patient in danger of death. But this danger, though great, is for the most part imaginary, provided that assistance be obtained in time. But that which desolates families, and which causes a physical degradation of the human race exposed to the attacks of malaria, is the chronic poisoning, which undermines the springs of life and produces a slow but progressive anæmia. This infection often resists all human therapeutic measures, and is even aggravated by the use of quinine, which is given during the recurrent paroxysms of fever. Quinine is, when given for a long period of time, a true poison to the vaso-motor nerves. The question, then, is to replace quinine, and the alkaloids which possess an analogous physiological action, by an agent the efficacy of which against chronic malarial poisoning may be greater and the dangers of its employment less.

A happy chance has led Dr. Magliori to the discovery of an agent of this sort, which was traditionally in use by certain Italian families. It is an exceedingly simple thing—merely a decoction of lemon. It is prepared by cutting up one lemon, peel and all, into thin slices, which are then put into three glassfuls of water and the whole boiled down to one glassful. It is then strained through linen, squeezing the remains of the boiled lemon, and set aside for some hours to cool. The whole amount of the liquid is then taken fasting. It is well known that in Italy, Greece, and North Africa, they often use lemon juice, or a decoction of lemon seeds, as a remedy in malarial fevers of moderate intensity; and in Guadaloupe they use for the same purpose a decoction of the bark of the roots of the lemon tree. All these popular practices tend to show that the lemon tree produces a febrifuge substance, which resides in all parts of the plant, but which would seem to be most abundant in the fruit. In fact, among the popular remedies employed against malarial infection, that which I have just described is the most efficacious, for it can be employed with good effects in acute fevers. But it is especially advantageous in combating the chronic infection, which is rebellious to the action of quinine, and in removing or moderating its deplorable effects."

Hardly had I learned of this method of medication, when I hastened to induce some proprietors in the Roman Campagna to try it with their farm hands; and, after witnessing the good results there, I endeavored to persuade practitioners to make a trial of the same treatment. I was ridiculed a little at first, for they thought it rather singular that a professor should be trying to popularize an old woman's remedy. In reply to that I answered that practical medicine would not have existed, had it not known how to treasure up from age to age the facts of popular experience; and I ventured to remark that, had the Countess de Chinchon waited until methodical researches had been made into the physiological action of cinchona bark, before popularizing the remedy, the use of which she had learned from the semi-barbarous Peruvians, in all probability humanity would still, as regards malaria, be dependent upon the medication practised in the middle ages. Happily these arguments had the desired effect upon certain distinguished practitioners, some of whom, especially in Sicily and Tuscany, have already collected together a tolerably large number of very encouraging observations. One of them, Dr. Mascagni, of Avezzo, tried the remedy in his own person, and succeeded in promptly curing an obstinate malarial fever which had resisted the action of quinine.

Gentlemen, in dealing with malaria we ought always to hold popular experience in high esteem, for we owe much to it. We owe to it the fact that we have been liberated from the paludal idea, and furthermore, that we have learned that it is often better, instead of trying to prevent the importation, for the most part imaginary, of malaria from distant marshes, to suppress its production in the soil under our feet or in that immediately surrounding us. We owe to it the knowledge, which we now have, that malaria rises up into the atmosphere only to a limited height, so that by placing ourselves a little above this limit in order to eliminate the possibility of the malaria being carried up to us by oblique atmospheric currents, we are enabled to breathe an air which does not contain this ferment, or which contains it only in insignificant amounts; thus one may even sleep in the open air during the night in very unhealthy districts without running any risks. The knowledge of this fact has led some peoples of Greece, and the inhabitants of the Pontine Marshes, to sleep in the open air on platforms raised on poles four or five metres (twelve to fifteen feet) in height. Some people in the Roman Campagna have built houses for themselves on top of the ancient tombs, the walls of which are perpendicular; the American Indians fasten their hammocks as high up as possible to the trees of the malarious forests; and very recently, the engineers of the Panama Railroad had little wooden huts built in the trees in order to procure safety against the terrible outbreak of malaria which occurred during the construction of that iron way. We owe, finally, to this popular experience the discovery of the specific action of quinine, and the consequent preservation of thousands and thousands of human lives. Why should we reject *à priori* and without investigation other useful data which it may yet present to our consideration? If we wish to make progress in this question of rendering malarious countries healthy, we must always hold before our eyes a double object: to find a means of prophylaxis which may be accessible to everybody; and, at the same time, to find a means, equally within everybody's reach, to overcome chronic malarial poisoning and its evil consequences. Science is still too far behind to permit us to hope that we shall soon succeed in discovering this second means by purely scientific researches. We ought, therefore, to gather together with great care all the facts which point to the possibility of a solution of this problem, and if the measures to which these facts point seem to be incapable of doing harm, we ought to try them boldly, and not be restrained by a false idea of the dignity of science. The social importance of the problem is too great to allow of its solution being retarded by the fear that scientific men may be accused of having been outrun by the ignorant. True science has none of these puerile susceptibilities; on the contrary, it deems it an honor to be able to seize all the observations of fact, whoever may have been their first recorder, to put them to the crucial test of methodical experiment, and to convert them into a new stepping-stone on the march of human progress.

Typhoid Fever and Tuberculosis.—Dr. Gral denies the existence, advanced by some authors, of an antagonism between tuberculosis and typhoid fever. If typhoid fever, he says, attacks a tuberculous subject, it does not run an abnormal course, but the tuberculosis assumes an acute character in consequence. Typhoid fever may be a cause of tuberculosis by creating a predisposition in the patient to this disease. In the stage of convalescence especially, the tubercular process often becomes very active.—*Deutsche Medicinal-Zeitung*, June 2, 1884.

FOOD RATIONS, IN HEALTH AND DISEASE, OF PERSONS CONFINED IN THE HOSPITALS, INFIRMARIES, AND PRISONS OF DIFFERENT COUNTRIES.

An Address Delivered at the General Session of the International Medical Congress, Copenhagen, August 15, 1884.

By Professor P. L. PANUM, M.D.,

COPENHAGEN, DENMARK.

(Special for The Medical Record.)

Physicians have hitherto devoted too little attention to the study of the proportions, both absolute and relative, of the albuminoid matters, fats, and hydrocarbons contained in the diet of the sick, the infirm, and prisoners, as well as in the separate dishes of which this diet is composed. A knowledge of these proportions is indispensable in establishing a rational dietetic régime for the sick, and also in determining whether the food, which is supplied according to fixed rules to the inmates of public institutions, is of a sufficiently nourishing character.

The objections which have been raised against the correctness of the average food rations, established by Voit and other physiologists as suitable for healthy individuals in good nutritive condition, are not well founded. The determination of the quantity of the albuminoid substances, fats, and hydrocarbons contained in the regular diet lists of hospitals, infirmaries, etc., is a powerful means of effecting improvements and reforms in the alimentation of the individuals supported in these institutions. But it is essential in all such calculations to observe every precaution necessary in order to obtain comparative results. Similar calculations regarding the different varieties of diet of patients confined in hospitals would be of great value as a means of recognizing and estimating the differences of opinion which still obtain concerning the alimentation of the sick, among physicians of the present day, in various countries.

Convinced of the great importance of this subject, the author advanced the following propositions:

First.—Endeavor to obtain information as complete as possible concerning the rations furnished to the healthy, or relatively healthy, inmates of hospitals, infirmaries, and prisons, as well as to the soldiers and sailors of different countries.

Second.—Endeavor to obtain, by means of similar information, and with the assistance of the hospital authorities in the different countries, comparative tables of the proportions of albuminoid substances, fats, and hydrocarbons contained in the regular diet lists, together with the indications for the employment of one or the other kinds of diet as used in the hospitals.

Third.—It would, however, be necessary to know first of all: (*a*) whether the individuals living upon a regulated form of diet are ever given any other food, whether this extra nutriment is given with regularity or not, and whether or not the amount of food so given can be determined with accuracy; (*b*) whether the distribution of these rations is so systematized that there is nothing in excess from which the hospital officers or attendants may derive an illegal profit; (*c*) whether the distribution is as just and equally proportioned as possible, and finally, whether the food for the attendants is prepared in other vessels than is that for the patients.

Fourth.—Obtain information as to the system employed to control: (*a*) the good quality of the ingredients, and (*b*) the preparation and distribution of the food.

Fifth.—Insist upon the necessity of according to the physicians unrestricted liberty in the regulation of the absolute and relative proportions of albuminoid substances, fats, and hydrocarbons which should be contained in the hospital diet. This liberty should be absolute, unfettered by any previous regulations, and free from interference on the part of the hospital authorities.

Sixth.—Encourage the publication in different countries of cook-books for the sick. These books should be in accord with the dietary customs of the countries in which they are published, and should indicate the proportions of albuminoid substances, fats, and hydrocarbons contained in the various dishes, in the same way as the doses of medicinal substances are indicated in the pharmacopœias.

Seventh.—Every physician should have suspended on the wall of his office a chart, after the model of König's, showing the quantitative composition of the ordinary aliments. In this way the importance of a rational dietetic régime would be constantly before his mind, and the chart would aid him in his dietetic prescriptions.

Eighth.—Those who make a study of popular hygiene, and who are able to do so, should occupy themselves with the preparation and rational composition of a dietary, which shall be sufficient and as cheap as possible to effect an amelioration of the lot of the poor.

Finally, the author said that he would be pleased to see the formation of an international association, composed of physicians of different countries, with the aim of applying the facts of alimentary physiology to the practice of medicine and to hygiene. The association would at the same time be subservient to the interests of science.

ON SOME DISORDERS OF NUTRITION RELATED WITH AFFECTIONS OF THE NERVOUS SYSTEM.

Being the Address in Medicine Delivered Before the British Medical Association at its Meeting in Belfast, Ireland, July 30, 1884.

By WILLIAM M. ORD, M.D., F.R.C.P.,

PHYSICIAN TO ST. THOMAS'S HOSPITAL, LONDON, ENGLAND.

(Special for The Medical Record.)

Subjects of discourse are assuredly not lacking when an address in medicine is to be delivered. To me, thinking of many—for example, of subjects historical, of subjects ethical, of subjects polemical—has come the final selection of a subject which, appertaining as yet very little to any one of these categories, has for some years very largely occupied my thoughts. A few minutes after I received the honor of being invited by your President to deliver this address, I happened to meet a friend whose advice I value very much. He at once suggested that I should talk about some subject to which my thoughts had been much directed, and specified certain disorders of nutrition related with affections of the nervous system which had certainly interested me very deeply, and were capable of general discussion. I took the advice, and set to work to write the paper. Presently I found that one subject with which I proposed to deal, the subject of chronic arthritis, was to be handled in the Section of Medicine by my able friend and colleague in the last International Medical Congress, Dr. Dyce Duckworth, and that the influence of nervous system on normal and abnormal nutrition was to be introduced in the Section of Physiology and Pathology, by Dr. Alexander. On reflection, I decided not to alter my intention. The fact that the subject which I had chosen was also in the thoughts of others promised me a critical audience; and in the multiplying of observations, probably all regarding the question from different standpoints, there was offered, so far, greater probability of apprehending the truth.

Let me invite you, then, to follow me in considering some perversions of nutrition of the body, or its parts, brought about, or appearing to be brought about, by the morbid agency of the nervous system.

I will ask you to let me put a sort of label on the matters of discourse, and to speak of them as Neurotic Dystrophies. They will include conditions of overnutrition, and of undernutrition, where the variation is of quantity rather than of kind; conditions of misdirected or eccentric nutrition, where the variation is of kind as well as of quantity.

The little used, or scarcely recognized term, dystrophy, will for my purpose cover these various perversions, and the adjective neurotic will indicate the aspect from which I wish for the moment to regard them. They will not be exclusively dealt with. This is inconsistent with the limits of an address. I shall only discuss some three or four instances, and discussing those shall rather review than attempt to prove. The general direction of my thoughts in relation to this subject may be best illustrated by certain neurotic dystrophies of joints and muscles.

Muscular atrophy, produced by joint-lesions.—M. Charcot, in last year's *Progrès Médical*, has treated, with that marvellous lucidity which belongs to him, of certain effects upon the nutrition and contracture of muscles, determined to all appearance by affections of joints. That the nutrition of the muscles of limbs in which the joints are affected by chronic and painful disease is often subject to impairment, has, as M. Charcot in his paper indicates, been long ago observed. But M. Charcot's method of treatment of the correlation gives to it a new etiological aspect. Let me quote two of his cases.

A man, aged twenty-three, in the telegraph service, having been previously healthy in all respects, had, about a year previous to examination, struck his right knee in jumping over a fallen tree. It is important to notice that the injury at the time did not appear to be severe, and that he walked afterward several miles without difficulty. At length he stopped for a time, and then found himself unable to walk without a stick. For a week afterward he kept his bed; the joint was swollen, but not very painful, but there was a remarkable loss of motor power in the limb.

At the time of M. Charcot's lecture on the case, the patient presented a weakness of the extensors of the legs, almost amounting to paralysis, associated with some loss of power and wasting of the rest of the muscles of the limb. While the whole limb was smaller in volume than the opposite limb, it was obvious that the anterior aspect of the thigh was most affected; the muscles of that region were limp, and presented no projection even at the moment of exertion.

Two things were then evident; paresis of the muscles of the limb, generally most marked in the triceps; a wasting of the muscles of the limb generally, again most marked in the triceps. Tested by electricity, the muscles and their nerves gave so little reaction, both to galvanic and faradic currents, that, to use M. Charcot's expression, one would have thought that the muscles were absent. There was a simple quantitative modification of both reactions, giving rise to the conclusion that the condition was one of simple atrophy, and not of a degenerative atrophy, with which the well-known "reaction of degeneration" would have been associated. To these tests M. Charcot added a third, namely, the application of the electric spark. He placed the patient on an insulated table, and connected him with a frictional electricity machine. A spark being drawn from the front of the thigh, or from the region of the vastus internus, an energetic contraction of muscles followed. Percussion of the right triceps produced an evident contraction, and percussion of the patellar tendon determined marked shocks, not only on the side of the percussion, but also in the two upper limbs, particularly in the left. There was no ankle-clonus. The muscles of the front of the right leg and calf contracted less forcibly under electrical stimulation than the muscles of the opposite side. M. Charcot states that, at the time of his demonstration, much of the loss of power had already disappeared under the steady use of electrical stimulation. Discussing the bearings of the case with the most delicate refinement of analysis, M. Charcot grasps at once the fact that the wasting and loss of power exhibited by the muscles was out of all proportion to the severity of the injury and the amount of suffering. He dismisses theories of propagation of articular inflammation to the neighboring muscles. He dismisses the theory of atrophy from prolonged inertia, and finds himself reduced to admit the existence of what he calls a deuteropathic spinal affection, giving rise to the paralysis and the atrophy. In the absence of the "reaction of degeneration," he finds himself unable to recognize any indication of a serious change in the anterior horns of the gray matter of the spinal cord, and is reduced to the suggestion of a kind of stupor or inertia of the nerve-cells. He is also reduced to the explanation of the exalted tendon-reflexes by the hypothesis that, while the cells of the affected region are in a state of torpor, there is a condition of exaggerated reflex excitability in the rest of the spinal cord.

The second case is that of a hair-dresser aged fifty-one. Here a chronic rheumatoid arthritis had affected the wrists, the shoulders, the ankles, the knees, the hips, the elbows, the fingers to a slight degree, and the cervical articulations in succession. There was neither pronounced inflammation nor pain; but there followed a rapid wasting and a great loss of muscular power. The wasting of muscles was unequal, falling chiefly in the extensors of the limbs. These showed the same loss of sensibility to electrical stimulation which had been observed in the other case, with one exception: the right vastus externus presented the reaction of degeneration. Many of the atrophied muscles were the seat of fibrillar contractions. Some of them, the left deltoid in particular, were excitable by simple percussion. The loss of power was in excess of the wasting. The tendon-reflexes were again strongly accentuated. To the conditions here enumerated M. Charcot adds, from observation of other cases, "contracture," tonic contraction of certain muscles, chiefly of flexors.

Summing up these and other cases, M. Charcot argues that the paresis, wastings of certain muscles, contractures of certain muscles, and the other associated symptoms, indicate an influence propagated from the affected joint or joints, incident on the spinal cord, and thence reflected to the muscles, giving rise in the one set of cases to contracture, where exaltation of function must be supposed in another set of cases to atrophy, where depression of function must be supposed.

If we accept M. Charcot's conclusions, we have in this group of cases a dystrophy of muscles, brought about by irritation commencing in joints more or less related with those muscles, propagated through centripetal nerves to the spinal cord, and reflected thence by centrifugal nerves to the muscles.

M. P. Berger has related for us some cases presenting the converse of the observations of M. Charcot just related. In M. Berger's cases, fracture of the upper part of the femur near the hip-joint was followed by arthritis of the knee; not attributable in any way to extension of inflammation through the intermediate tissues. M. Berger's observations would lead to the establishment of the possibility of a reflex influence reversing the path of the influence just quoted. In other words, we have before us observations suggesting that joints being inflamed may, by a reflex influence, give rise to dystrophies of associated muscles; and that bones and surrounding textures being injured may give rise to dystrophies of neighboring joints. Such considerations carry us on to search for the middle term; to examine if there be any evidence indicating a direct morbid influence of the spinal cord on the nutrition of the component parts of limbs in common; and secondly, they may lead us to inquire whether the nutrition of joints and other parts of limbs may be affected by influences propagated from viscera; that is to say from parts which are not components of limbs.

Chronic rheumatic or rheumatoid arthritis as work of nerve-influence.—Having this in view, I will ask you to accompany me in considering chronic rheumatic arthritis as a possible work of nerve-influence. I use this term, chronic rheumatic arthritis, because I am speaking in Ireland in the presence of many men who must be well acquainted with the work of Adams, of Dublin.

Chronic rheumatic arthritis is, as you will also know, but one of many names given to an affection of joints, spoken of by the non-medical public as rheumatic gout. The morbid lesions of this disease are of a kind justifying completely the application to them of the term dystrophy; for while they include destructive inflammation of articular cartilages, and subsequently of the bone beneath, they include also hypertrophic changes in the synovial membrane, and in the periosteum around the articular surfaces.

Here, once more, I must refer to the work of M. Charcot, whose name is associated with the remarkable observation that a form of chronic joint disease, presenting both the atrophic and the hypertrophic lesions of chronic rheumatic arthritis, forms a part of the phenomena of tabes dorsalis. It is true that the atrophy predominates enormously; but the hypertrophy can always be recognized by any one who may care to study with care the specimens of joint-trouble exhibited by M. Charcot. The essential lesion of tabes dorsalis, as at present recognized, lies in the spinal cord, and is, so far, a central nervous lesion. But the actual seat, you will remember, is not in the gray matter, but in columns of fibres, which, to all appearance, are the channels of centripetal influence, flowing, at least in part, from the voluntary muscles. In fact, it is quite possible to argue that the joint-lesion may be here the result of reflection of irritation, propagated to the gray matter of the spinal cord by the diseased muscle-representing fibres of the posterior root-zone; that, in other words, muscles, subjectively presented to the gray matter as in a state of irritation, can induce by reflection a dystrophy of joints. If there be any possible acceptance of the idea that joints, being irritated, can, by reflex trophic influence, affect the nutrition of muscles; and that muscles, or their centripetal nerves, being irritated, can produce, also by reflex trophic influences, dystrophies of joints, we can hardly stop short of accepting a further suggestion to the effect that some part of the central nervous system, presumably some part in the spinal cord, presides, in a common sense, over the nutrition of organs so closely associated as joints and muscles, perhaps also over that of bones.

Turning our attention to what is known of the direct influence of the central nervous system upon the nutrition of muscles, we know already that there is a very fair certainty of the existence of a definite relation between certain affections of the anterior horns of the gray matter of the spinal cord and atrophic affections of muscles.

Associated with an acute inflammation of groups of cells in the anterior horns, are found the phenomena of infantile and essential paralysis; associated with an inflammation of the same anterior horns, differing from that just mentioned in being chronic, and differing probably in its method, are found the phenomena of progressive muscular atrophy. Infantile paralysis and progressive muscular atrophy have each so distinct a grouping of symptoms as to confer on each a marked clinical identity, and on each an assured independence of the other. Nevertheless, they have in common one important factor, wasting of muscles; but the wasting of muscles is, if we may judge by their electrical reactions, not brought about by the same process in the two cases. In infantile paralysis, the reaction of degeneration leads us to infer that the nutrition of muscular (centrifugal) nerves is seriously involved. In progressive muscular atrophy, this reaction does not appear, there being only a diminution of electrical reaction proportionate to the loss of muscular fibre.

Joint lesion in progressive muscular atrophy.—My friend, Dr. Gulliver, of St. Thomas's Hospital, an inheritor of the observing faculty and accuracy of his celebrated father, has recently communicated to me, quite independently of this address, the notes of a case in which a joint-lesion appeared as a part of the phenomena of progressive muscular atrophy.

In studying this disease, I had long thought that there were indications, in many cases, of affections of joints as well as of muscles. Dr. Gulliver and I have often conversed on the subject, and when the patient, whose case I will now relate, came under his notice, he lost no time in bringing her to mine.

K. M——, a married woman, aged fifty, came under treatment in June, 1884. Of the family history nothing was ascertained. Her previous history presented nothing important, save that she had never had rheumatism. For six or seven months she had noticed a loss of power in the left arm, but had been able to carry on her occupation of laundress till within the last six weeks. About five months ago she began to experience difficulty in speaking, which increased till, at the time of observation, she was unable to articulate in any intelligible way. She had also a growing difficulty in swallowing, with impairment of the use of the lips in movements other than those of articulation, for instance, in blowing out a candle, and she had dribbling of saliva. Three months ago—at least, three months after the commencement of muscular feebleness—she began to experience pain in the left shoulder-joint, greatly increased by raising the arm, actively or passively. At the time of observation, the left arm was found to be much wasted, particularly in the forearm, and in the thenar and hypothenar eminences. The hand had the claw-shape characteristic of progressive muscular atrophy; it was the *main en griffe* of Duchenne; and she could not oppose the tips of the fingers to the tip of the thumb. She could not raise the left arm to the horizontal position, and all attempts to do so gave rise to much pain in the shoulder-joint. All movement involving the shoulder-joint, whether performed voluntarily or effected by other persons, gave much pain. The joint showed no coarse changes; there was no affection of the right arm or of the legs; the muscles of both arms answered equally to the galvanic current; those of the left appeared to react a little readily under the faradic; the knee-jerk was more active than usual in both legs. The tendon-reflexes of the arms were investigated, but the results were not definite. She could not speak, being able to produce nothing more than a monotonous inarticulate sound; she could not protrude the tongue, or blow out the lips. The palate was motionless; and she swallowed with difficulty.

Although the order of affection of the muscles of the arm is not recorded, the case is clearly one of progressive muscular atrophy, in which the bulbar affection is predominant. And while, as regards the limbs, the left upper extremity was alone affected, the painful state of the left humeral articulation indicates the existence of a definite change in the nutrition of a joint belonging to the same area of innervation as that of the affected muscles; and, so far as it goes, the case tends to show that one central nervous affection may give rise to concomitant dystrophy of joint and muscle.

(To be continued.)

Treatment of Ununited Fracture of the Tibia.—Dr. Eugene Hahn writes, in the *Centralblatt für Chirurgie* of May 24, 1884, describing a new procedure employed by him with success in the treatment of pseudarthrosis of the tibia. The case was one of compound comminuted fracture, in which there had been a loss of a considerable amount of bone-substance, the two ends of the tibia being separated about three inches. Various attempts had been made to secure union without success, until it occurred to Dr. Hahn to implant the broken end of the fibula, which bone had been fractured higher up than the tibia into the medullary canal of the upper fragment of the tibia. He did so, and union took place between the two bones with the result of restoring the usefulness of the limb. The patient wore a light retention splint on the leg, and was able to walk about with ease.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 23, 1884.

THE RESCUE OF LIEUTENANT GREELY, THE EFFECTS OF THE ARCTIC CLIMATE, AND THE QUESTION OF CANNIBALISM.

THE Arctic regions have, by the enterprise and heroism of Commander Schley, been compelled to surrender the living remnants of Greely's party, and some of the dead bodies of victims of this unfortunate expedition. The facts of the fitting out of this expedition in the interest of science, the lamentable failure of our Navy Department last year, and the year before, to place supplies where they were the most needed, and the terrible chapter of suffering and privation which succeeded the retreat of the party in August, 1883, from Lady Franklin Bay to Cape Sabine, and their long incarceration in the latter locality—a chapter of desolation and misery of which the half has not yet been told—are sufficiently familiar to the readers of THE RECORD.

If it should be proved that the necessity of cannibalism was added to the horrors of the last year's experiences of this party, the story of hardship and wretchedness would seem to be about as black as reality could make it, or even imagination could paint it.

A private interview with Lieutenant Greely, at his former home, has enabled us to obtain a somewhat clearer insight into the physiological and pathological effects of prolonged residence in the Polar regions, as well as the straits to which the Greely party were finally reduced. He ascertained that such sojourn, by inhabitants of warmer climates who are in good physical trim, is for a brief term of years compatible with a high state of all the organic functions, in which there is entire freedom from diseased manifestations of every kind; but there is a decided limit to the endurance by Europeans and Americans of such extreme prolonged cold. The system is at first, and for a long time, by an admirable series of internal adjustments, braced up against the rigors of climate; but after the first year a considerable deterioration in muscular and nervous energy, and in the calorigenous processes of the economy is experienced. The severity of the second winter was found by the party somewhat harder to bear, but the experience of the previous winter had taught them how best to fortify and protect themselves, and husband their forces. The third long Arctic night, in which the thermometer was never less than three below zero, and much of the time was down to forty or fifty below, would, under the most favorable circumstances, have been a painful season to the party; vital reaction was quite perceptibly lessened; muscular tone was impaired, rendering exertion difficult, and rheumatisms began to prevail. Could the party, however, have had plenty of food, and full and good shelter, they would undoubtedly have all been living at this day. Lieutenant Greely, in reply to an interrogatory, affirmed his doubts as to whether his men, if well provisioned, could have continued to live at Fort Conger more than five years. The constitution of the average American is not capable of prolonged continuous adjustment to more than zero cold, and such acclimatization could only come about after a series of generations where the law of survival of the fittest should operate, and in correspondence with a radical change in organization, in which nutritive and muscular development should predominate over cerebral development; in other words, nature has shown us in the mentally dwarfed but physically hardy Esquimaux, the type of organization best fitted for living in those sep tentrional latitudes. It, however, is no less a matter of fact that the inhabitants of meridional climes admirably adapt themselves temporarily to the most extreme cold. In the retreat from Moscow, in 1812, the Italian regiments stood the cold better than the Germans, and notably better than the Russians, who were accustomed to the climate.[1] The Turks presented the same relative immunity at the siege of Sebastopol. Longet, from whom these facts are taken, remarks that the aptitude to resist inclement temperature is acquired and lost in turn; that people nurtured in temperate or cold climates, who go to the torrid zone to live, are much less sensitive to the cold for a time after their return to their native country, though this lessened susceptibility disappears after a year or two.

As man can live amid intense surrounding cold only by keeping his internal temperature at about 98½° F., all the calorigenous centres—which comprise every living element or cell in every part of the body—are stimulated to greatly augmented activity; the respiratory, digestive, and assimilative processes are performed with unwonted energy; the heart's action and the circulation are notably quickened. Lieutenant Greely remarked that breathing air of such intense coldness had something of the effect produced by breathing pure oxygen; as for pulmonary troubles he heard no complaint of them while the party was at Fort Conger, in Lady Franklin Bay, at a latitude of about 82°, where the first two years were spent; even simple catarrhs were unknown, the only thing from which the men suffered being occasional rheumatisms, and stiffness of the muscles and joints.

The party had ferocious appetites during all of this long sojourn in the North, each man eating with relish three meals of animal food and two lunches every day, and craving fats, though not to the extent which some Arctic travellers report. Not even when the thermometer marked 60° below zero did these men indulge in crude blubber or tallow candles, which tradition has designated as the customary food of Arctic voyagers; nor was even pemmican regarded as a rare and dainty dish by them. Canned meats, of which they had an abundance during the first two years, and a steak or ragout from the walrus, seal, or polar bear, were prized as the

[1] Longet: Traité de Phys., t. ii., page 540.

essential conditions of well-being. As for spirituous liquors, they were used with great moderation and doled out to the members of the expedition as occasion seemed to demand, and only when some unusual exertion or exposure brought extraordinary fatigue or prostration; as means to fortify the system against cold or brace it up for forced marches, whiskey, rum, and other alcoholic stimulants were regarded as of little benefit.

The party slept well during all their long stay at the North, except during the last few months of physiological misery, when the pangs of hunger and the weakened, disordered condition of their anæmic brains precluded refreshing sleep; in the case of some of them the horrors of scurvy made their state more deplorable still.

As for the prolonged agony at Cape Sabine, sympathizing, pitying humanity would fain draw a veil over those appalling scenes which can be imagined, but cannot be described. If men driven to madness by long fasting, the only means of sustenance available being strips of seal-skin, shrimps, and Arctic moss, their scanty rations being exhausted; entertaining the forlorn hope that if they might hold out only a few weeks longer deliverance would come to them; if under such circumstances there were no alternative but death or anthropophagy, it may seem to us that death would be preferable to life sustained on such terms, but we can realize neither the hunger, nor the desperation, nor even the impelling strength of the most imperious instinct of our nature.

In justice to Lieutenant Greely, it must here be stated that he denies all knowledge of cannibalism as having been practised by any members of his party. If some of the men, to save their lives, fed on the carcasses of their companions, it is a matter for which they are individually responsible, not he.

The results of the autopsy of Lieutenant Kislingbury are quite significant. We make no comment on the sworn statement of the physicians, except to call attention to the fact that the body was stripped of muscle where the muscle was the thickest; the pectoral, gluteal, dorsal regions, the thighs, legs, and arms in their entirety, were denuded of flesh, and there was evidence that this was done with a knife; not that the soft parts were gnawed away by some wild animal; moreover, the viscera were intact. Virtually the same thing was done with the body of Private Whistler, as also proved by post-mortem examination.

There is, we hardly need say, other evidence, obtained from members of the rescuing crew, that goes to establish the fact of cannibalism at Cape Sabine. It is proper to say, however, that the results of the examination of the contents of the Kislingbury stomach cannot, by themselves prove absolutely that human flesh was eaten. In this connection we would refer to the letter of Dr. Heineman (see page 216), in which some very suggestive questions are asked.

In considering this revolting subject, it is the scientific or physiological side that claims our attention. Can the practice of cannibalism by civilized men—men of naturally human and refined natures—be conceived as *possible* under any circumstances? What are the psychological antecedents and accompaniments of anthropophagy? Is cannibalism ever justifiable, and was it justifiable in the Greely party, in the straits to which they were reduced? In other words, what is the *moral* aspect of the question?

1. Can the practice of cannibalism, by civilized men, be conceived as possible? It is true that no one of the readers of this journal can easily imagine the affirmative of this question in its application to himself; looking at it, as he must, from the high normal plane to which, through ancestral inheritance and moral culture, countless evolutionary ages have raised him. And doubtless, the average civilized man could not be brought to an act of cannibalism by any process of *acute* starvation. Lord Ross has remarked that even the savage Esquimaux will starve rather than eat human flesh.

But here we must emphasize the work *acute*, as opposed to *chronic* starvation. Not one week or two can easily undo the work of ages, as manifested in the development of brain, and the noblest powers of mind. Amid the general languishment of the organs and tissues, the brain and nervous system the longest maintains its integrity.[1] There is prostration, there is hebetude of the nervous functions, but delirium comes late, if at all, and when it makes its appearance, the unhappy sufferer is too feeble to make any energetic effort to save himself.

But it is not so in *chronic* starvation, that may be many weeks, if not months, in effecting the deterioration and destruction of the organism. In all ages, and among all nations, there have been histories of famine in connection with sieges, droughts, etc., where prolonged inanition has driven men to cannibalism. Such facts show that anthropophagy *has* been possible under circumstances of deepest misery; and this brings us to the second question: What are the psychological accompaniments of cannibalism? Under this head we must be brief. There is no doubt that the functional integrity of the brain and mind is dependent on sufficiency of good food and a healthy nutrition. He that enjoys *most* the cerebral acquisitions which he has inherited and cultivated, is the man who, *cæteris paribus*, is the best nourished. Conversely, long continued mal-nutrition effects what Hughlings-Jackson calls gradual dissolution in the "topmost layers" of the highest centres; the individual is now "lost to his surroundings," is "defectively conscious." In other words, the victim of chronic inanition becomes a degraded being, and is capable of lapsing into a stage where brute instincts and brute appetites predominate.

In the famine which attends on long sieges, mothers have been known to devour their own offspring, whose lives they had taken. "Verily," as Longet observes, "where the maternal instinct perishes, every other noblest instinct must have departed."

The psychological antecedent and accompaniment of cannibalism, then, is a state of positive frenzy or insanity, from which every element of moral responsibility is lacking. The words "delirium of famine" appropriately designate this condition, and are so used by some authors.

To apply this thought to the particular case under consideration, who will say that the life at Cape Sabine did not present all the conditions requisite for engendering

[1] According to Chossat's experiments, the nervous system scarcely loses 1.9 per cent. of its substance. Recherches Expérimentales sur l'Inanition. Paris, 1843.

in some, if not in all the members of the party, the necessary psychical and physiological antecedents of cannibalism? It seems more probable, however, that the eating of human flesh was comparatively a late occurrence in the dreadful experience at Cape Sabine; this means of sustaining life not being resorted to till their regular rations were almost if not quite consumed. It will be remembered that Kislingbury died virtually of starvation, and that in his stomach there was not a vestige of animal or human flesh.

3. Is cannibalism ever justifiable? Was it justifiable at Cape Sabine? Every right-minded person will, we think, say "Yes!" If the question of *irresponsibility* is settled in the affirmative, then all discussion of the moral aspect of cannibalism is foreclosed—there can be no immorality in the case. If any or all of this band of devoted heroes, who so barely escaped being *martyrs* to science, were saved by eating the dead bodies of their comrades, with a deliberate suppression of an irrational sentimentality, and not without due reverence for the dead, we say that we regard the act under the circumstances as justifiable. We believe that no pretence has ever been made that these men murdered any of their companions for such a purpose.

That we have not misrepresented the terrible state of mental dilapidation of the party at the time they were found is apparent from all the testimony. Lieutenant Powell says that "they were all in such a dazed condition that they did not realize that they were rescued until they had been given some ptarmigan, and then they began to curse the rescuers for not giving them more food."

THE PROPHYLAXIS OF MALARIA.

The address on malaria, delivered by Professor Tommasi Crudeli, at one of the general meetings of the International Medical Congress, and which we are enabled, by special arrangements made in Copenhagen, and by our cable facilities, to present in full to the readers of The Record this week, is one of unusual interest. It deals with questions of vital importance to humanity and which especially concern very nearly the inhabitants of our own land. There is scarcely a township in the United States where malaria does not count its victims, and in many portions of the country it is as dreaded a scourge as it is in Italy or on the west coast of Africa. Even in the immediate neighborhood of New York pernicious remittents are not unknown, and deaths from this cause figure in nearly every table of vital statistics. It is on account of the interest of the subject, as well as because of the deservedly high reputation of the author, that this one of the general addresses of the Congress was selected for presentation in full to our readers.

The author is strongly opposed to the paludal theory of malaria, to which, indeed, but few authorities of any weight at the present day incline. We, at least, in this country need no array of arguments to disprove the notion that the malarial ferment is formed exclusively in marshy ground and is thence carried by the wind to other dryer and more elevated regions. An ample and a sad experience has taught us that it is usually indigenous to the soil on which we live, and that no exceptional degree of moisture is necessary to its production.

It will, perhaps, be a matter of surprise to some who remember the confident predictions made a few years ago of the extinction of malaria by the cultivation of the eucalyptus-tree, and who have not noticed the growing silence of those who were formerly most enthusiastic in their advocacy of this measure, to read the disparaging comments of the author upon the results obtained. The setting out of eucalyptus plantations is attended with a great expense, which, he claims, is by no means commensurate with the benefits realized, for oftentimes the good effects are purely imaginary. The measures which afford the greatest hope of success in the task of purifying a malarious soil consist, in the author's opinion, in thorough and systematic drainage and forced cultivation of the ground. Sowing the land thickly with grass offers a barrier to the escape of the malarial poison, but is in the nature of the case an imperfect method of securing immunity from infection; for of course a breach is made in the ramparts every time that a spade is plunged into the sod, and the enemy is never slow in forcing its way through the broken barriers.

The results of Professor Crudeli's experiments in the matter of individual prophylaxis are those which offer the most encouragement. This is, indeed, the first difficulty to be surmounted; for, as he rightly says, it requires time and the presence of man in order to repress the formation of the malarial ferment, and unless we can insure man from the attacks of the disease during this preparatory period, the reclamation of the lands can never be accomplished, at least by civilized nations. The excessive use, or abuse of quinine, like the abuse of mercury, is nearly as baleful in its effects as the disease which it is designed to overcome, hence the desideratum that exists for some prophylactic remedy that is at once a real prophylactic and at the same time readily obtainable and suited for popular use. Arsenic, which the experiments detailed in the address would seem to show does possess prophylactic virtues, is a drug that could hardly be put with safety into the hands of the laity, despite the alleged existence of the Styrian toxiphagi. Whether the decoction of lemon will prove on more extended trial to possess the powers that are claimed for it, time and experience can alone determine. The author shows that he is endowed with the true scientific spirit in being ready to examine into the merits of a popular remedy of so simple a nature. And we certainly have reason to hope that such conscientious investigation and painstaking research will meet with their reward. The sons of Italy were once foremost in the ranks of science, and Crudeli and his fellow-laborers are doing much to restore to their country her proud eminence among the nations of the earth.

OUR CABLED REPORT OF THE INTERNATIONAL MEDICAL CONGRESS.

We are happy to announce the completion of our cable report of the International Medical Congress held in Copenhagen. The most notable address is one which we have the pleasure of presenting in full—that by Prof. Crudeli, of Rome. Prof. Panum's address is given in full abstract, while the remaining proceedings are incorporated in the general cable report, including the abstracts of addresses by Sir William Gull and Virchow.

We may be perhaps excused for congratulating ourselves on such a successful accomplishment of a plan for presenting to our readers on this side of the Atlantic a full and authentic report of one of the most notable Congresses held for a long period. We have been enabled to demonstrate what can be done by cable by giving an accurate report of the doings of a scientific body in which subjects of a purely technical character are discussed.

We believe we have succeeded in presenting to our readers a *résumé* which is sufficiently comprehensive and instructive to warrant us in making the effort. The abstracts of addresses and papers have been carefully prepared by our correspondent with this end in view, and we are convinced they can speak for themselves.

As will be seen, the meeting was a success from every point of view—the subjects and addresses were well selected, and the different orators did them full justice, thus giving a high scientific tone to the meeting. Nor were the sections behindhand as to subjects of interest or of speakers to present them. This is evident through some of the reports which we give of sectional work.

It would be impossible, of course, to present in the time allotted, even with the best of cable facility, an exhaustive report of the proceedings, but sufficient has been done to give our readers a fair idea of what was accomplished by the Congress as a whole. Further reports by mail will give fuller detail. The social element of the meeting was what it should be, and though generous to the full point of royal hospitality it did not interfere in any manner with the strictly scientific work. The selection of the next place of meeting, at Washington, D. C., was good, and as was predicted the invitation on behalf of the profession of this country was received with a becoming cordiality. It remains now for the profession of this country, by every means in its power, to make the next session of the Congress a success, and demonstrate in due form its appreciation of the honor conferred by the selection.

CRUELTY TO THE PAUPER INSANE.

Of late years the worst accounts regarding the treatment of the insane, in the East and North at least, have related to the pauper insane in the smaller almshouses and prisons. The last story of cruelty toward this class comes from Pennsylvania. Dr. Thomas G. Morton, for the State Committee on Lunacy, has sent the following letter to every physician in the State:

PHILADELPHIA, August 16, 1884.

My Dear Doctor: Two instances of cruel treatment of insane patients in charge of private parties have recently come to the knowledge of the Committee on Lunacy. In one case an old man was found naked in an outhouse in a very secluded spot of the State, where he had been confined for more than thirty years chained by the leg. In the other case neither the public nor the Committee had any knowledge of the inhumanity practised upon an old man, who had likewise been chained for more than a quarter of a century, and it was not until his death that the particulars were brought out and made public.

In view of these facts, the object of the committee is to find out if any such cases are known or believed to exist, and if so, to send them to the State hospitals for the insane, where they can receive humane and proper treatment, and that if you have any reason to believe any such insane are concealed and badly treated, we will, on private information from you, investigate such cases and take the necessary steps for their transfer. Any communication will be, if desired, considered confidential.

Yours, very truly,

THOMAS G. MORTON, M.D.

Since the publication of the above, another case of a similar character has been published. It was that of a young man who had been confined for some time in the Berks County Almshouse. He had a ball of heavy weight chained to his leg.

The facts revealed by the Pennsylvania Committee teach again the lesson that the pauper insane ought not to be kept anywhere except in institutions provided especially for them, and under responsible medical management. Poverty may indeed compel counties to care for some of their own insane poor in workhouses. But where this is necessary there is no excuse for not having careful and frequent supervisions.

Although medical philosophers and reformers may reason, demonstrate, and protest they very well know that there is a bad political method at the bottom of most of the abuses they condemn. The people must be educated and then aroused before thorough reform can take place.

THE CRIME OF A MIDWIFE.

The *Louisville Medical News* states that a physician in that city recently returned a death certificate in which the cause of death was given as placenta previa, adding that the death was "superinduced by the criminal carelessness of a midwife." It appears that the deceased had engaged the services of a midwife. She had suffered from hemorrhage for several weeks before labor came on, but the midwife paid no attention to it. When the labor pains began, the hemorrhage was very profuse. Still the midwife did nothing, except leave her patient, saying that she would return soon. She never came back at all; and the patient died.

The *News* makes the above the text for a very vigorous attack upon the midwife in general, and the German midwife in particular. As for remedies the editor betrays a cynical desire to see all midwives poisoned or put out of the way by some means.

The suggestion is made, however, and it is one we cordially endorse, that all midwives be licensed, and, before being licensed, be obliged to give evidence of some education and skill. At present the chief education which the midwife receives is the highly subjective one of having had from five to ten babies herself.

An Enthusiastic Electro-therapeutist.—According to the *Medicinal Central-Zeitung*, the well-known (?) therapeutist, Dr. Seimus, has gone to Marseilles for the purpose of setting up electric machines in the wards of the hospitals there. By the disengagement of ozone he hopes to disinfect the air, and perhaps assist in curing the patients.

News of the Week.

Professor L. Hermann, of Zurich, has been called to the chair of Physiology at Berlin to succeed V. Wittich.

The Celebrated Physiologist, Professor Carl Vierordt, of Tübingen, has resigned, and his place is to be filled by Professor Grützner, of Bern.

More Cholera Commissions.—The Roumanian Government has sent Dr. Maccovich as a "commission" to Marseilles, in order to study the cholera.

A Plague Commission.—The Russian Government has sent Dr. Batorsky to Bagdad, for the purpose of investigating the plague, now prevalent there.

A London (Canada) Medical Society.—The medical men of London, Canada, have recently met and organized an association for social and scientific purposes.

Women as Internes in the Paris Hospitals.—It is stated in the *Revue Médicale*, that women are soon to be admitted to the examinations for positions as internes in the Paris hospitals.

The Characteristic Enterprise of The Medical Record finds another illustration in its cable report, in its issue of 2d inst., of the proceedings of the British Medical Association at its meeting in Belfast, Ireland, on July 29th and 30th.—*Medical Age.*

Journalistic Changes.—The *Canadian Practitioner* has a new editorial staff. Drs. Cameron and Nevitt have resigned, and Drs. J. E. Graham and W. H. B. Aikins have taken their places. Dr. Wright continues upon the staff. The *Pacific Medical and Surgical Journal* and the *Western Lancet* have consolidated.

Virchow *vs.* Pettenkofer.—Professors Virchow and Pettenkofer are busily arguing with each other upon the subject of cholera. The gist of their differences lies in this: Virchow is a contagionist, Pettenkofer is a localist. That is to say, the latter believes that no specific germ can produce cholera unless there is a specific local condition to favor it.

Nepotism at the Massachusetts General Hospital.—Some interesting correspondence has been going on in the *Boston Medical and Surgical Journal* relative to the above subject. It is charged that the medical board appoint as *internes*, members of their own or their friends' families, and that appointments are matters of personal favoritism rather than of real merit. There seems to be some truth in the charge, but it is not denied that the *internes* are good men.

The First Case of Yellow Fever which has appeared in this country during the present season was reported on August 15th, and occurred at Key West, Fla. The patient was an officer on board the U. S. vessel Galena. The Galena was ordered at once to Portsmouth, N. H., while the patient was taken in charge at Key West. It is now six days since the case was reported, and there is as yet no further appearance of the disease.

The Medical Details of Cannibalism.—The account of the examination of the body of Lieutenant Kislingbury, as given by two physicians of this State, and telegraphed all over the country, were shocking in the extreme. We cannot see the necessity of medical men lending their special knowledge for the elaboration of horrible details regarding the supposed Arctic cannibalism. Is science or the world any better for knowing that the pectorales muscles were eaten and the recti abdominales were not?

The Head of Campi.—The experiments of Dr. Laborde, which we have already referred to, upon the head of the assassin Campi, were rather tame after all. It was an hour and a half after the execution before fresh blood was injected into the carotid arteries. The face naturally became suffused, some electrical reactions were obtained, but no reactions of the special senses, and no reflexes. The assassin had agreed before death to make some signal if the transfusion brought back any consciousness. Campi's brain was turned over to the Anthropological Society.

Adulterated Beer.—Imported, and especially Bavarian beer, has been supposed to be exceptionally pure. This is not the case, however, according to recent reports. These say that so many complaints have been made of adulterated beer that the Bavarian Government has taken the matter in hand and ordered an investigation to be made. All breweries are to be subject to inspection. At Memmingen the inspection has resulted in the condemnation of thirty-three brewers to pay fines ranging from $50 to $250, according to the degree of impurity of their beer. Three others were sentenced to eight months in prison.

The Canadian Medical Association—The British Association for the Advancement of Science.—The Canadian Medical Association meets next week, August 25th, 26th, and 27th. The meeting of the British Association for the Advancement of Science will commence on Wednesday afternoon, August 27th, after the close of the Canada meeting. Over fifty of the physicians and surgeons who have promised to come out for the British meeting, have been invited to attend the Canada meeting, and more than half have accepted, among them being Mr. Lawson Tait, who has promised to deliver an address on "Abdominal Surgery."

A Cure for Red Noses.—The sun which shines for all is sometimes a factor in producing red noses. It is very appropriate, therefore, that the New York *Sun*, which also shines for all, should devote its columns to discussing remedies for the congested organ. The following are three "cures" suggested by as many correspondents:

"A remedy which I have used with best results is the following: Take of vaseline one ounce, precipitated sulphur, two drachms. Mix well and apply to the affected part night and morning, rubbing in well. Continue the application for one or two weeks and the redness will disappear. Physician."

"For the benefit of 'A Reader,' Marshall County, W. Va., I would suggest that a good strong brine might effectually and permanently cure the red nose of which he complains. W. H. H."

"Another Plan. A remedy for red noses. Keep on drinking and it will turn purple. Slap Sticks."

THE CHOLERA.—The cholera continues to decrease in extent and violence at Toulon and Marseilles. It has, however, now spread to over forty places in France, and to a large number of places in Italy. While the disease has become milder in the two cities mentioned, it shows a malignant type in many of the small towns which it has reached.

THE FIRST DISCOVERER OF THE CHOLERA GERM.—Naturally, the questions of priority as to the discovery of the alleged cholera bacillus now appear. A correspondent of *The Lancet* puts in a claim for the late Professor Pacini, of Florence, the discoverer of certain corpuscles in the skin bearing his name. In 1854 he wrote to the *Italian Medical Gazette* as follows: "Examining minutely the different parts of the gastro-enteric tube of subjects dead from cholera when in the algid state, I was forced to the conviction that that epithelial lesion is covered by nothing but a very simple organism of extreme tenuity, which I shall call 'microbe,' a term generic and modern, and with special reference to the disease in question, 'cholerigenous microbe.'" This discovery was more quickly and thoroughly appreciated by foreigners than by its author's own countrymen, and in 1865, on the next cholera visitation, Pacini wrote: "When my scientific labors, having made the tour of Europe, will have returned, arrayed in foreign garb, to Florence, they will have permission to enter the schools, and then we shall be enjoying the tranquil repose of Trespiano—in our grave, in short." This bitter forecast, says *The Lancet*, has been verified almost to the letter, Pacini's doctrine, rehabilitated by the German Cholera Commission, being now adopted by his compatriots and taught in the Istituti Pathologici of Italy a year after his death.

We must dissent from the opinion that Pacini discovered the cholera bacillus. He very likely saw some minute organisms in the intestine, as many others have done, but the cholera bacillus, according to Koch's description, is revealed by a one-twelfth oil immersion with an Abbe condenser, the tissue being dried and stained with fuchsin. It is quite safe to say that Koch is the Columbus of the Comma-Bacillus, whatever its significance may turn out to be.

SUGGESTIONS RELATIVE TO EPIDEMIC CHOLERA.—The Massachusetts State Board of Health has issued a circular under the above title. It contains an excellent account of the measures to be taken by individuals and municipalities in order to prevent cholera. The following disinfectants are recommended: For clothing, towels, bedding, and other textile fabrics, a solution of bichloride of mercury, 1 part to 1,000; carbolic acid, 1 part to 30 of water. Subjecting to a temperature of at least 212° F. (100° C.) for an hour, either by boiling or baking, is recommended as quite efficient when practicable. It would be better still to burn all soiled clothing. For water-closets, urinals, sinks, and cesspools: solution of bichloride of mercury (corrosive sublimate), 1 part to 1,000 of water; solution of carbolic acid, 1 part to 30 or 40 of water; solution of chloride of zinc, 1 part of liquor zinci chloridi, U. S. P., to 200 of water. For the disinfection of excreta the choleraic discharges should receive special attention. It is therefore recommended that such discharges be received in metallic or earthen vessels and treated with the solution of bichloride of mercury, 1 to 1,000, or by the chloride of zinc solution. Undoubtedly the better mode of treating the discharges is by complete destruction by fire. For this purpose, when practicable, the erection of small furnaces, stoves, or crematories is desirable wherever cholera hospitals are established. In consequence of the fluidity of the excreta it would be preferable to receive them into sawdust, or other light combustible material previous to burning. Bodies of persons deceased from cholera should be wrapped in cloths saturated in a solution of bichloride of mercury previous to burial. For the disinfection of houses sulphur is recommended, as advised in previous circulars of the board. Effective disinfection by burning sulphur requires eighteen ounces to each space of one thousand cubic feet. The sulphur should be broken in small pieces, burned over a vessel of water or sand, so as to avoid danger from fire, and, if the room is large, it should be put in separate vessels in different places. The room should be tightly closed for six hours, and then aired; it is better that the room should be warm than cold. Of course, efficiently disinfected air is, during the process of disinfection, irrespirable. Most articles may be disinfected in this way, if hung up loosely in the fumigated chamber, although it would be an additional safeguard to expose anything thick, like a bed-mattress, to prolonged heat at a temperature of 240° F.; and, indeed, *heat* must, with our present knowledge, be considered *the best disinfectant*. With this end in view, local boards of health are advised to procure furnaces and laundries, as is commonly done in other countries, to be used for the sole purpose of disinfecting articles which have been exposed in the infectious diseases, as recommended in the "Ninth Annual Report of the State Board of Health" (pp. 255 et seq.). Of course, a much simpler disinfecting furnace than that described will answer every purpose. For ordinary use, in disinfecting houses, the sulphur process is the best.

PRINCE BISMARCK'S PHYSICIAN, DR. SCHWEININGER, who was some time ago made a professor, has now, it is said, been given an order of nobility and made Professor in the Faculty of the Berlin University, with authority to deliver certain courses at Charité. *Apropos* of Dr. Schweininger, the German papers publish in the humorous column the following story: "A servant in Münich was showing the sights to a country visitor. The latter wanted to know all about the figures and statues on the University Building. Rather than confess ignorance his city friend gave the names of distinguished contemporaries to the various gods, goddesses, and other immortals in stone. 'And that figure,' he said finally, pointing to a very classically dressed statue on the façade of the left wing, 'is Dr. Schweininger.' 'Aha!' said the admiring visitor, 'but where then is his coat?' 'Oh,' replied his friend, 'since he cured Prince Bismarck, the people have sent for him from all over the country, and he has had to travel so hard that he has worn off his clothes!'"

CRITICISING THE LOUISIANA STATE BOARD OF HEALTH.—*The Mississippi Valley Medical Monthly* thus criticizes the Louisiana State Board of Health, which started off this year with such alluring promises: "This Board," it

says, "has neither the ability (financial) nor the authority to enforce such quarantine regulations as this great Valley has a right to demand. Nevertheless, in the face of these facts and in opposition to the expressed will of the National Board of Health, the Marine Hospital Service, and the Sanitary Council of the Mississippi Valley, together with muttering threats of shot-gun quarantine, this Board has persistently arrogated to itself the right to enforce its rules and compel the commerce of the United States to yield tribute to its support. It has disturbed the workings of the National Board of Health; has rendered the Marine Hospital Service almost powerless in that locality, and has done much to prevent the enactment of proper laws for the enforcement of quarantine by the Congress of the United States." According to the same journal, the Louisiana State Board of Health, which thus undertakes to guard the Mississippi Valley, receives only $6,000 a year besides "a scanty and contested pittance" from quarantine and registration fees.

Regulating Midwives in the City of Berlin.—The following regulations have been adopted by the Berlin Police Department. They contain important suggestions for the municipalities in this country: "Midwives, on commencing practice, are to notify the same personally to the Bezirks-Physikus within fourteen days, and at the same time to lay before him (1) their license; (2) the day-book; (3) the last edition of the Prussian "Handbook of Midwifery for Midwives"; (4) the instruments prescribed by the latter. They are required to treat their cases strictly in accordance with the instructions given in the handbook. They must keep a day-book after a prescribed pattern in which cases must be entered, and they must fill up the columns accurately, or permit the medical man they call in to do so. Besides the instruments prescribed, which must be kept clean and ready for use, they must always have such disinfecting material as is ordered. Every case of puerperal fever, as well as every maternal fatality, must be notified within twenty-four hours of verification of diagnosis or death to the Royal Sanitary Commission. They must also submit to subsequent examinations once in three years."

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Reports of Societies.

International Medical Congress.

EIGHTH SESSION,

Held at Copenhagen, Denmark, August 10–16, 1884.

BY CABLE TO THE MEDICAL RECORD.

(Concluded from page 188.)

THURSDAY, AUGUST 14TH—FIFTH DAY.

AT the General Session, 3.30 P.M., SIR WILLIAM GULL, of London, delivered an address

ON THE INTERNATIONAL COLLECTIVE INVESTIGATION OF DISEASE.

Speaking of the importance of the subject, he maintained that its proper consideration promised greater advances in knowledge than by the ordinary methods. The time had come when organized co-operation, as against scattered individual efforts, should be encouraged. This was, in fact, one of the purposes of the Congress and other similar medical organizations. The field of scientific medicine was too large to be compassed by any other means. The amount of work that could be accomplished by a systematic direction of numerous workers was practically without limit, and was proportionately valuable. By such means facts could be accumulated on a large scale, and be utilized accordingly. In conclusion he referred in detail to the admirable work of the Committee on Collective Investigation in the British Medical Association, and urged that the scheme be extended throughout the scientific world, in order that the results might be centralized, if need be, in the different medical congresses hereafter to be held. The subjects of acute rheumatism and contagiousness of phthisis had already been worked up by different committees of investigation, and had given some remarkably valuable results. The English and German Committees had both chosen the latter subject, and their conclusions were strikingly consistent.

MEETINGS OF SECTIONS.

Section on Surgery.—There was a discussion of the subject of

ANTISEPTICS IN SURGERY.

Professor Lister, of London, being absent, the discussion was opened by PROFESSOR ESMARCH, of Kiel, who, after some general remarks upon the principle of antiseptics, alluded to the advantage of permanent dressings for wounds. The rule was to thoroughly cleanse and disinfect the parts and then seal them with antiseptic coverings to prevent the subsequent entrance of germs. This dressing was kept applied as long as possible, consistent with cleanliness and the absence of constitutional disturbance. The general practice of German surgeons was to use catgut ligatures, the latter being completely absorbed in the wounds. Professor Esmarch applies the permanent dressings after main vessels are secured and before the removal of the tourniquet. He does not think it necessary in the large majority of cases to use drainage-tubes, but supports the deeper parts and keeps them in contact by pressure. Openings are left for the escape of drainage into the bandages, which are sterilized by dry heat and corrosive sublimate. Other antiseptics are occasionally used, but preference is always given to bichloride of mercury. The parts are sometimes supported by glass splints until healing is accomplished by first intention. The general treatment carried out is based upon the grand principles of absolute rest, perfect cleanliness, and thorough drainage.

Professor Mosetig-Moorhof, of Vienna, advocated the use of iodoform as an antiseptic in the dressings, but preferred simple cold water during operations.

Dr. Schede, of Hamburg, thought well of iodoform, but his best results were obtained when corrosive sublimate was used. With the latter erysipelas vanished and septic troubles were almost unknown. He was in the habit of employing the corrosive sublimate solution in the proportion of one to five hundred, and had yet to meet with the first case in which indications of poisoning showed themselves, although there were sometimes symptoms of tenesmus. Even children bore the corrosive sublimate dressing without any bad results.

The general principles of antiseptic treatment were endorsed by Professors Mikulicz, Neudorfer, Buchanan, and Schelkley, who followed with remarks, the only differences noted being in the methods of application.

Professor Koeberlé, of Strasburg, used only clean linen with which he wiped the wounds, and had noticed no erysipelas when the open method of treatment was followed.

Professor Plum said that the Danish surgeons agreed in the main with their German confrères, although the cost was somewhat of an objection to Esmarch's plan. Cleanliness was, after all, at the bottom of all antisepsis, and the soap and the brush, when properly employed, would work wonders. It was a question, after all, how simple we could make the matter, and how we could divest ourselves of useless paraphernalia.

Section on Medicine.—Professor Lépine, of Lyon, read a paper entitled "Clinical Observations on the Toxical Principles which are formed in Living Organisms," giving a full *résumé* of the literature of the subject, and presenting illustrations of the relations of cause and effect on the commoner variety.

Professor Leibermeister, of Tübingen, followed with a communication on the antipyretic treatment of acute infectious diseases, advocating the utility of employing the different well-known methods in particularly well-selected cases.

The subject of antiseptic treatment of the same diseases was next presented by Professor Bouchard, of Paris, who also discussed the different methods and their applicability to individual cases.

A general discussion then followed, in which Professors Rothé, Lepine, and Pribram joined.

Professor MacEwen, of Glasgow, read a paper on "Orthopedic Osteotomy," which was discussed by Professors Agston, Chiene, Schede, and Mr. Bryant and Dr. Robin. The general sentiment was in favor of MacEwen's operation in proper cases.

Section on Ophthalmology.—Papers read: "Determin-

ation of Refraction by Ophthalmoscope," by Professor Schmidt-Rimpler, of Marburg. This paper was duly discussed by Dr. Noyes, Mr. Berry, Dr. Yuler, Sattler, Grut, and Liebreich. On the "Artificial Maturation of Cataract," by Dr. Ed. Meyer, Paris; discussed by Drs. Moore and Samuelson. On "Infantile Blennorrhœa, its Prevention and Treatment," by Dr. Christensen, of Copenhagen. On "Inflammation of the Eye," by Dr. Martin, of Bordeaux.

Section on Diseases of Children.—Prof. Hirschsprung, of Copenhagen, presided. A paper was read by Dr. P. Rupprecht, of Dresden, on "The Choice of Antiseptics in the Treatment of Wounds in Children." He was followed by Dr. Sofus Meyer, of Copenhagen, who read a paper on the "Prophylactic Treatment of the Ophthalmo-blenorrhœa of the New-born." A paper was read by the President, Prof. Hirschsprung, on "Intestinal Invagination and its Comparative Frequence in Different Countries;" and one on the same subject by Prof. Ribbing, of Lund. Dr. A. Jacobi, of New York, read a paper on "Primary Sarcoma of the Kidney in the Newborn."

A GRAND BANQUET.

At five o'clock in the afternoon a grand banquet was tendered the members of the Congress by the Municipal Council of Copenhagen. Fourteen hundred guests were present. The tables were set in a large tent erected for the occasion upon the Custom House quay. The interior of the tent was decorated with the flags and coats-of-arms of the different nations. The tables were profusely ornamented with flowers, another evidence of the warm hospitality of the Danish ladies. After the courses had been finished, speeches were made by President Panum, and by Pasteur, Paget, and Virchow. Many of the guests went upon an excursion by steamers to Tivoli. The entertainments of the evening closed with a grand display of fireworks and electric lights. The whole city joined enthusiastically in the spectacle.

FRIDAY, AUGUST 15TH—SIXTH DAY.

PROFESSOR VIRCHOW'S ADDRESS.

PROFESSOR R. VIRCHOW, of Berlin, delivered an address entitled "Metaplasia."

He said that at the beginning of the present century the processes of life were considered to be merely chemical. Life and thought were bound to certain matter in the blood, which, becoming solid, formed tissues. Even Schwann said that cells were formed by a sort of crystallization of the plasma. These chemical doctrines were of English origin. John Hunter spoke of "plastic lymph." These doctrines were supported by the then physiological views of nutrition. The plasma was thought to supply food directly to the tissues, in fine, to feed them. As a consequence, the healing art was thought to consist mainly in regulating nourishment, *i.e.*, the supplies furnished the plasma. Virchow made the first step toward the cellular pathology thirty years ago, when he announced his doctrine *omnis cellula e cellula*. He said that the task for nourishment was to keep the cells alive. These cells then formed tissues and, indeed, to them belonged all the formative functions. The speaker contrasted the nutritive with the formative processes.

Differences in the matter supplied affected nutrition, but the formative process was the same, with the most varied nourishment. All organic operations, said the speaker, occur within cells, never outside of them. The speaker defined automatic nourishment of cells, showing that their nutrition supply was regulated by certain automatic checks, so as to be kept at the proper mean. He then spoke of the phenomena of growth and the production of new tissue forms, to which he gave the term "metaplasia." He described the various theories of bone formation, and showed the difference between ossification and calcification. He spoke also of the formation of bony marrow, which being a tissue of changing form, furnishes a good example of metaplasia. He explained the pathology of osteo-porosis and osteo-malacia. He referred briefly to the subject of the development of tumors. Lastly he spoke of the white blood-globules, and of their ability to form new tissue. In them metaplasia reached its furthest limits.

Dr. Lewis A. Sayre, of New York, gave some demonstrations of the application of his plaster-of-Paris bandage for the treatment of spinal disease, and was followed by Professor Tommasi Crudeli, who showed some microscopic specimens of red blood-corpuscles taken from the human subject suffering from malaria. The infected corpuscles responded to aniline and some of these were seen to contain colored particles. These he considered germs of bacilli. Healthy corpuscles refused the stain and contained none of the particles referred to.

MEETINGS OF SECTIONS.

Section on Medicine.—Professor Rosenstein, of Leyden, presented a paper on "Malarious Infection in Man," which was discussed by Professors Flint, Ewald, and Mahomed. Professor Grancher, of Paris, next read a paper on "Subacute Pneumonia," dwelling mostly on its clinical significance.

Section on Ophthalmology.—Dr. Gayet, of Lyons, read a paper on "The Results of Great Losses of the Substance of the Cornea," which was discussed by Professors Berry, Grut, Noyes, and Nieden. The subject of "Latent Squint" was presented by Dr. Grut, of Copenhagen, and was discussed by Dr. Noyes and others.

Section on Diseases of Children.—In the morning there was a joint session with the Section on Hygiene, and in the afternoon the regular session was held.

Dr. Schepelern, of Refsnaes, Denmark, read a paper on "The Treatment of Chronic Diseases of Children at Sea-Coast Hospitals," which was followed by a communication from Dr. Engelsted, of Copenhagen, on "Sea-Coast Hospitals for Scrofulous Children," especially with regard to the Refsnaes Hospital in Denmark.

In the afternoon session, Dr. Rauchfuss, of St. Petersburg, read a paper on "Croup Clinically Considered as a Well-limited Morbid Entity." This was discussed by Professor Virchow and others.

RECEPTION BY THE KINGS AND QUEENS OF DENMARK AND GREECE.

In the evening a reception was given the Congress at the Christiansborg Palace, by the Kings and Queens of Denmark and Greece. The affair was a brilliant one

and the most bountiful hospitality expressed the royal appreciation of the distinguished guests. After the enjoyment of a sociable converse and musical concert, the members were entertained at a sumptuous supper, at which the King of Denmark proposed the toast of the foreign members, which was felicitously replied to by Sir William Gull.

SATURDAY, AUGUST 16TH—SEVENTH DAY.

THE NEXT CONGRESS TO MEET IN WASHINGTON, 1887.

At 3.30 P.M. the Congress took up the subject of the place of next meeting. The Committee to whom the subject was referred, reported back a recommendation that the invitation to hold the next meeting in Washington, U. S., be accepted. There was a warm debate over the subject; the English members strongly supported the decision, however, and it was finally voted by a considerable majority to meet in Washington in 1887. After the vote was announced, Dr. J. S. Billings thanked the Congress in warm terms, and expressed his gratitude at the hospitality which had been extended to the guests. He was followed by Virchow and Sir Risdon Bennett.

The General Session concluded this day by congratulatory addresses in the different official languages. In French, by Professor Rauchfuss; in English, by Professor Jacobi; and, in German, by Professor Hirschsprung.

Professor Panum closed the Congress at five o'clock.

SECTION WORK.

Section on Diseases of the Eye.—Dr. Bjerrum, of Copenhagen, read a paper on "Refraction in Infants."

Professor Holmgrén, of Upsala, read a paper on the "Color Sense."

Mr. Yuler, of London, demonstrated the use and advantages of McHardy's perimeter and of Frost's artificial eye.

Dr. Klebs showed the method of using the electromagnet in removing bits of iron from the eye.

Section on Medicine.—Dr. Proschowsky gave a demonstration of sphygmographic and cardiographic tracings.

Dr. Joh. Butzen, of Copenhagen, read a paper on "The Different Action of the Japaconitine, the Pseudaconitine, the French and the German Aconitine."

Dr. Roussel, of Paris, read papers on the "Direct Transfusion of Living Blood," and upon "Medical Hypodermic Injections."

Dr. Maurice Dupont, of Paris, read a paper on the "Medical Use of Condensed Air in the Form of Baths and Douches." He showed illustrations of his new apparatus.

Professor Granger-Stewart, of Edinburgh, read a paper on the "Influence of Acute Infectious Diseases upon the Kidneys and their Functions."

There was a joint session of the Sections on Diseases of Children and Hygiene; the papers read were as follows: "The Normal Increase of Weight through the Latter Childhood," by Mr. Mating Hansen and Dr. Wahl, of Denmark; "Meningitis Tuberculosa in the First Year of Life," by Dr. Medin, of Stockholm; on the "Influence of Cold on Diseases of Children," by Professor Logroux; on an "Easily Curable Form of Infantile Spinal Paralysis," by Professor d'Espine.

At one o'clock the various sections adjourned, and after a lunch visited several of the hospitals of the city.

EVENING ENTERTAINMENTS.

In the evening a reception was given at the National Establishment. It was preceded by a concert and followed by a ball and supper. The total number of guests present was eighteen hundred.

The attendance in nationalities was as follows: Danes, 450; Swedes, 150; Americans, 64; English, 120; French, 118; Germans, 234; Austrians, 35.

The Congress is looked upon as a decided success, and as having been most admirably managed. The social features were attractive, but the hospitalities were judiciously lavished, so as not to interfere and crowd out the scientific work.

Obituary.

JOSEPH JANVIER WOODWARD, M.D.,

PHILADELPHIA, PA.

COL. JOSEPH JANVIER WOODWARD, Surgeon in the United States Army, died Tuesday morning near Philadelphia. He was born in that city in 1832. He received his education at the Philadelphia Central High School, where he was given the degree of A. B. in 1850, and that of A. M. in 1855, having acted as the valedictorian of his class. After receiving the first degree he entered upon the study of medicine, and in the spring of 1853 he was graduated from the University of Pennsylvania. He practised medicine in Philadelphia until August, 1861, when he was appointed an Assistant Surgeon in the regular army. He had already attained considerable prominence in his profession through the publication of a number of treatises on abstruse subjects, especially on the use of the microscope in the practice of medicine. He subsequently attained such eminence in this particular branch that he was regarded as one of the leading authorities in certain departments. He invented an instrument by which the myopic condition of the eye can be determined with accuracy. He served in the war, and distinguished himself by his gallant conduct. He was brevetted Captain, Major, and Lieutenant-Colonel on March 13, 1865, for faithful services.

On July 28, 1866, he was made Captain and Assistant Surgeon, and was promoted to the rank of Major and Surgeon on June 26, 1876. In 1866 he was selected for the important duty of editing the "Surgical and Medical History of the Rebellion." With this great work his name will always be inseparably connected. He also published a number of papers of great interest and value. Among them were "Address on the Medical Staff of the United States Army." "Remarks on Croup and Diphtheria." "Typho-Malarial Fever; Is it a Special Type of Fever?" "Remarks on Photographic Micrometry." "Application of Photography to Micrometry, with Special Reference to the Micrometry of the Blood in Criminal Cases." Report on "Medical Literature," and report on "Causes and Pathology of Pyæmia." When President Garfield was shot, on July 2, 1881, Dr. Woodward was in Washington in the Surgeon-General's Bureau. He was one of the surgeons first summoned to the bedside of the wounded President. He remained in constant attendance there until September 7th, when he retired in company with Drs. Reyburn and Barnes.

During his residence in Philadelphia Dr. Woodward was a member of the Philadelphia County Medical Society. He was also a member of the American Medical Association, of which he was the Second Vice-President in 1875; of the American Academy of Sciences, and of the Medical Association of the District of Columbia.

He was a delegate to the International Medical congress in Philadelphia in 1876.

Dr. Woodward will be especially remembered for his description and differentiation of typho-malarial fever, for his remarkable work in micro-photography, for his microscopical studies of the blood, and for his work in connection with the "Medical and Surgical History of the War."

Dr. Woodward was a man of positive views and somewhat abrupt though not unpleasing manners. He was an untiring and conscientious worker, never sparing himself, and he doubtless wore himself out before his time.

Reviews and Notices.

Traité de l'Affection Calculeuse du Foie. Par le Docteur Jules Cyr, Médecin Inspecteur adjoint à Vichy. Paris: V. Delahaye et Lecrosnier. 1884.
A Treatise on Calculous Disease of the Liver. By Dr. Jules Cyr.

The large experience which Dr. Cyr's position at Vichy has afforded him in diseases of the liver entitles him to rank as one of the authorities in such affections. The present work on gall-stones is the result mainly of his own observations, and in consequence bears a mark of originality which adds greatly to its readableness. At the same time he has not ignored the labors of others in this field, so that the monograph, in spite of the author's modest disclaimer, may justly be regarded as embodying all that is of value respecting biliary calculi. The chapters on diagnosis and treatment are especially valuable.

History of the Discovery of the Circulation of the Blood. By Henry C. Chapman, M.D., Professor of Institutes of Medicine and Medical Jurisprudence, in Jefferson Medical College. Philadelphia: P. Blakiston, Son & Co. 1884.

An interesting essay, in which the author shows that the discovery of the circulation of the blood, like all other great discoveries and movements, was the result of a gradual intellectual growth and not due solely to the acumen of Harvey. The credit of the discovery does not belong, in his opinion, to England, for Harvey, though by accident of birth an Englishman, was in thought Italian, and lived and died a student of Padua. Moreover the earlier workers, to whose investigations Harvey was indebted for the ideas which led to his grand discovery, were chiefly Latins or Italians.

The Relation of Animal Diseases to the Public Health, and Their Prevention. By Frank S. Billings, D.V.S., Graduate of the Royal Veterinary Institute of Berlin; Member of the Royal Veterinary Association of the Province of Brandenburg; Honorary Member of the Veterinary Society of Montreal, Canada, etc. New York: D. Appleton & Co. 1884.

The question of the susceptibility of man to infection from animal diseases is one that has begun to attract considerable attention of late among hygienists and physicians, and that promises to become of still greater importance in the future. The more the subject is studied the more intimate is seen to be the relation between diseases of man and of the lower animals, and a knowledge of some at least of the more common infectious diseases of animals is daily becoming more necessary to the physician who seeks not only to cure but to prevent sickness in the human race. On this account the appearance of the work before us is timely. It treats of the higher purposes of veterinary medicine in seeking, by a careful study of animal disease, to prevent its extension to man. The work is divided into three parts, treating respectively of the diseases of domestic animals, the history of veterinary medicine, and the means of prevention of disease. Nothing is said of treatment, as the book is not intended to be a treatise on veterinary medicine, but is rather adapted to the wants of the hygienist and of all those interested in the subject of preventive medicine. The author is very dogmatic in his assertions, and is apt at times to be rather severe in his strictures on some of his co-laborers in the same field; but this is a fault, if fault it be, common to all pioneers in a new subject who are thoroughly in earnest and who are of necessity, as the author confesses himself to be, enthusiasts. The book might, we think, be somewhat condensed with advantage, for to the general reader whose time for studies of this sort is limited, a volume of 440 octavo pages is a little formidable.

Brain Exhaustion, with some Preliminary Considerations on Cerebral Dynamics. By J. Leonard Corning, M.D. New York: D. Appleton & Company. 1884.

In these days of hurry and worry the questions considered in the book before us have assumed a measure of importance unknown to our fathers. We perhaps work no harder, but we work more irregularly and with less regard for the necessity of relaxation, than those before us did. The demands upon our thinking apparatus are very great, but we take little care to see that the apparatus is kept in good working order. But the time comes when the brain refuses to work at such high pressure, and if then it is urged on beyond its strength it either stops or breaks away from all control. In this work on the exhaustion of the brain, the author presents, in a very clear and intelligent form, the various causes and symptoms of the complaint, and points out the principles upon which its treatment should be pursued. He insists very strongly upon the damage to the mental faculties resulting from the custom of late and protracted evening amusements and the loss of sleep entailed thereby. He also urges the necessity of a meat dietary for brain-workers, and shows very clearly the mental superiority of meat-eaters over vegetarians. The subject of the book is indeed worthy of careful consideration, and it is presented by the author in such a pleasant and attractive style that the reader will find himself entertained as well as instructed.

WAS HUMAN FLESH EATEN BY ANY OF THE GREELY PARTY?

To the Editor of The Medical Record.

Sir: I address this note with a view of possibly obtaining some more definite information concerning the microscopical examination of the contents of the stomach of Lieut. Kislingbury, and of the other Arctic dead. According to the reports of the physicians, pieces of epidermis, etc., removed from the stomach and intestines, were recognized as unquestionably human.

I presume that the eaten flesh was subjected to some mode of preparation before mastication; it is also certain that the digestive process must still further have changed the tissues, and that, in spite of the general preservation, a certain amount of disintegration and probably decomposition must have followed.

Was it possible to make such a microscopical examination as would justify the unequivocal deduction, from this alone, that the "chyme mass" was of human origin? Or was the conclusion a partial inference from the condition of the body and the reports of the survivors, which leave no doubt in the mind of any of us as to the sad occurrence of cannibalism?

In the interest of "expert" testimony, and exact science, the latter of which so often unjustly suffers obloquy from the former, can our colleagues, on the basis in question, leave their conclusions unqualified, that the stomach contents were undoubtedly human?

I am yours truly,

H. N. Heineman, M.D.

49 West Fifty-seventh Street,
August 19, 1884.

Correspondence.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION, AT BELFAST, IRELAND

(From our Special Correspondent.)

BELFAST, August 2, 1884.

THE Belfast meeting may be pronounced a success. A large number were present, and the general and sectional meetings were well attended. Belfast is a large town, and possesses ample accommodation for a crowd of visitors. The building in which the meetings were held—Queen's College—is one particularly well adapted for the purpose to which it has been devoted during this week, and the college grounds, together with the adjoining botanical gardens, formed a pleasant resort for members in the intervals between the meetings. The only disadvantage has been in the location of the college, viz., between one and two miles from the chief hotels. Some could get accommodation near the place of meeting, but this was necessarily limited, and the majority of those present had to seek quarters in the centre of the town. To get to the meetings, therefore, they either had to walk, ride by tram, or take an Irish car or other vehicle.

The number of members of the Association present has been about five hundred odd, and if to this be added the medical visitors and delegates, and the medical students of Queen's College (who were permitted to attend), the total number probably exceeded six hundred. A number of American physicians were present, among them being Dr. Lewis H. Sayre, of New York; Dr. John Shoemaker, of Philadelphia; Dr. Frederick Hyde, of Cortland (delegate from the American Medical Association), and Dr. A. Jacobi, of New York. In all, I think, some sixteen American medical men were present. From other distant localities there also came representatives, viz., from Guernsey, Paris, Geneva, Jamaica, and even India.

On the first day, Tuesday, members began early to assemble, register their names and addresses, get their tickets, and ask for letters and telegrams at the temporary post-office erected in the porter's lodge at Queen's College for the convenience of members during the meeting. The latter, as in previous meetings, proved a very great convenience to members and others present, and the post-office official placed in charge of it had indeed a very busy time. Some little hitch occurred at first in the arrangements for the registration of members, owing to the official books and tickets having been delayed by the railway companies. This was promptly got over by the printing and issuing of temporary tickets, which were duly exchanged for the proper ones when the latter arrived.

The proceedings might be said to formally commence with the first general meeting, which took place in the library of Queen's College, and was well attended. The library is a detached building, standing in the college grounds, and the large central hall surrounded by a gallery afforded ample seating space. This room was devoted to the general meetings and to the Council meetings. The first general meeting was preceded by a short Council meeting, at which the following gentlemen were present: Chairman—Mr. C. G. Wheelhouse, President of the Council; Dr. James Cuming, President-elect of the Association; Dr. A. T. H. Waters, President; Dr. T. Bridgwater, Dr. Alfred Carter, Dr. Alfred Carpenter, Dr. Deas, Dr. G. F. Duffey, Dr. Balthazar Foster, Dr. Grigg, Dr. C. E. Glascott, Dr. Eyton Jones, Dr. W. G. V. Lush, Dr. McVail, Dr. W. Moore, Dr. C. Parsons, Dr. Edward Waters, and Messrs. C. Macnamara, J. Prankerd, and T. Sympson.

At the Council meeting 88 gentlemen were elected members of the Association, and other business was transacted.

The general meeting opened at 3 P.M. Dr. A. T. H. Waters, President, in the Chair. He proposed that the minutes of the last meeting should be taken as read, which was adopted unanimously. Dr. Waters made a few remarks on the prosperous state of the society and its continued increase in numbers. During the past year 1,040 new members had been added to the Association, while only 139 members had died. The total number was now nearly twelve thousand—to be exact, he believed it was 11,800.

He then resigned the chair to Dr. Cuming. A vote of thanks to Dr. Waters was then proposed by Dr. John Moore, of Belfast, seconded by Dr. Felce, of London, and carried unanimously. Dr. Waters was elected a Vice-President of the Association for life.

Mr. Wheelhouse then proposed the adoption of the report of the Council and the financial statement for the year 1883. Some exception was taken by some gentlemen to the sum of £1,660 put down as paid to contributors to the *Journal*, and it was asked for what was this sum paid. It was remarked that most of the original contributions were offered gratuitously to the *Journal*, and asked whether this amount was paid for editorial matter? It was explained that it was paid for scientific reports and various matter furnished not by the editor or his assistants, but by various gentlemen all over the country. Details could not be furnished of the individual articles for which payment was made, but they were such as were approved by Mr. Ernest Hart in his editorial capacity, and by the *Journal* Committee. The financial statement submitted showed that the total editorial expenses were £3,000 odd, yearly. The financial statement and the report of the Council were adopted.

Mr. Macnamara, of London, was then proposed by Mr. Wheelhouse, of Leeds, as Treasurer of the Association for the ensuing three years, in the place of Dr. Wade, whose term of office had expired. The motion was made by Dr. Rogers and supported by Dr. Edward Waters, and carried unanimously. A letter was read from the late Treasurer suggesting improvements in the mode of signing cheques. Dr. Wade thought there ought to be an additional signature before moneys were paid away. The letter was referred to the Council for consideration. A motion to that end by Dr. Ward Cousins was passed, and then a motion was made by Dr. McVail (in the absence of Mr. Dix) providing for the payment out of the general funds of the Association of the travelling expenses of the members of the Council to and from the Council meetings. Under the new constitution of the Association, as amended last year, the Council is now to be a body representative of the Association at large, each branch electing its own representative. Dr. McVail urged that it was desirable that the members of the Council should attend, and to insure the distant members doing so, their expenses should be paid. It had been objected that it was unnecessary, and that there were in every branch men of means and leisure who could attend; but Dr. McVail contended that these were not the men that were wanted, but they wanted representatives of the rank and file of the profession. It had been urged that distant branches might nominate metropolitan members to represent them, but this defeated the very object of having a representative Council. After prolonged discussion and speeches by Dr. Alfred Carpenter, Mr. George Brown, Dr. Bernard O'Connor, Dr. Balthazar Foster, Mr. Brindley James, Mr. Ernest Hart, and others, the motion was finally negatived, as it was when brought forward at the Liverpool meeting last year. Some angry feeling was exhibited in the course of the discussion. Several speakers maintained that the provincial members did not attend well, and could not be expected to, if they not only had to neglect their practice but pay their own expenses. It was alleged that the management was practically in the hands of the metropolitan members. At some meetings it was stated that a very large proportion of those present

were metropolitan members, owing to non-attendance of provincial members. Mr. George Brown quoted figures from the *British Medical Journal* in support of this view, and energetically exclaimed that "the members of the Council were dummies." Mr. Hart maintained that the average attendance of the country members as compared with the metropolitan was very good. One gentleman exclaimed that "those were the dummies who did not come."

The meeting then adjourned for dinner, and reassembled in the library at eight o'clock. The building was illuminated with the electric light generated by an engine temporarily erected for the purpose.

On assuming the chair Dr. Cuming delivered his presidential address, which you have already published, and which was warmly received, and the usual vote of thanks was then passed.

Lengthy discussion then took place on motions brought forward by Dr. Bernard O'Connor, which were successively negatived. The motions were to the effect of permitting members of branches to elect members to represent them who did not necessarily reside within the area of the branch, so that distant branches could be represented by members who resided near London. The last motion fell through for want of a seconder.

A somewhat disorderly scene then took place in connection with a motion brought forward by Mr. George Brown. He was finally declared out of order, and the meeting terminated between ten and eleven o'clock.

At the second general meeting on Wednesday, at eleven, it was reported that Dr. Balthazar Foster had been elected President of the Council for the ensuing three years. A vote of thanks was passed to Mr. Wheelhouse for his past services in the same capacity. It was announced that Cardiff had given an invitation to hold the next annual meeting in 1885 in that town, and this was unanimously accepted, and Dr. W. T. Edwards, senior physician to the Glamorganshire and Monmouthshire Infirmary, chosen President-elect. Dr. Edwards returned thanks. Dr. Ord then delivered the Address in Medicine (which we publish in our present number). A vote of thanks to Dr. Ord was then proposed by Dr. A. T. H. Waters, of Liverpool. He was sure they would all agree with him that the address had been a very able and interesting one. Dr. Ord had travelled over a wide field, and had treated his subject with great success. The important relations of reflex action in the human system had long occupied their attention, but he thought Dr. Ord had placed before them more forcibly perhaps than it had been done before the important influence of the nervous system in the production of chronic rheumatoid arthritis. He (the speaker) had seen cases of this disease in elderly people, which he felt fully convinced must be traced to neurotic origin. He would only remark that the influence of the nervous system on the production of disease no doubt required very deep, careful, and profound study; and perhaps the lines of thought which they had had laid down by Dr. Ord would give them much material for reflection. He thought an address of that kind was not only eminently scientific but essentially practical.

Professor Gairdner, of Glasgow, seconded the resolution. He came there very early that morning in order to obtain a good place to hear Dr. Ord, but when the President of the Council pounced upon him at once with an offer of the duty he was then performing, he felt in the position, not of the early bird that caught the early worm, but of the early worm snapped up by that watchful and ever wary bird the President. He could say that, having followed the course of Dr. Ord's investigation, he had never read a page, word, or line of his writing which did not bear the mark of something to be very carefully and deliberately thought over. Under those circumstances, it would be a very poor compliment to Dr. Ord to there enter into anything like a discussion upon the address they had heard. As a teacher of medicine, he (the speaker) was compelled by his office, as it were, to study systematically the turns and currents of opinion, and it was extremely interesting to him to note, and to accentuate the fact, that the drift marked by such addresses as that to which they had listened was decidedly in favor of solidism. All he could say there then was that Dr. Ord had made a most powerful pleading in favor of the neurotic origin of disease, which they had been in the habit of ascribing to other sources. They were all insensibly biassed by the systematic views which they took of things, but they must admit that the facts of science were too complex for them, and would bear looking at from many points of view.

The motion was carried by acclamation.

Dr. Ord having acknowledged the vote in a few words, the new Council for 1884–85 was announced, and the Association adjourned.

In the evening a *conversazione* was given in Queen's College by the President of the Association and the Executive Committee. In spite of the unfavorable weather —it raining heavily during the evening—this was very numerously attended. To this ladies were admitted. The college was brilliantly illuminated by the electric light, and presented a festive appearance. The rooms were crowded to overflowing.

At the third general meeting Dr. Redfern delivered his address. At the fourth general meeting Dr. Kidd delivered his address on "Obstetrics," which was cordially received and the usual vote of thanks given.

At two o'clock the concluding general meeting was held in the library, when the discussion on medical reform was continued by various gentlemen, and the reports of the Parliamentary Bills Committee, Habitual Drunkards Committee, Scientific Grants Committee, and the Collective Investigation Committee.

In the evening a reception by the Mayor in the Ulster Hall was numerously attended.

SECTIONS.

Section on Surgery.—Sir W. MacCormac delivered the address in the Section on Surgery, and spoke of the advances in visceral surgery—cerebral, thoracic, abdominal—and also of gastrostomy, the early history of which was disastrous, but which he now considered justifiable, and referred to two recent cases of malignant disease in which he had performed the operation with considerable benefit to the patient and prolongation of life. He recommended the operation to be performed early enough in such cases, and considered antiseptics gave a good chance. He spoke of Howse's plan, of dividing the operation into two parts, as removing practically all risk. He then spoke of the radical cure of hernia, but preferred the term radical treatment. He said the operation was not new but old; it was easily done in that for strangulated hernia as a step in the operation. This was a great advantage, and he thought in strangulated hernia the radical treatment, by excising a portion of the sac, should always be done. In congenital inguinal hernia he believed a radical cure could be effected. He then referred to the operation of thyroidotomy. It was one of the most formidable and difficult operations in surgery. Its dangers were mainly two, viz., sepsis and bleeding. To avoid the latter he suggested the ligature of the vessels first. He questioned Kocher's views as to the liability to myxœdema and cretinism as a sequel of removal of the gland; but he said that neither of these results had ever followed partial removal of the gland, and in many cases this was sufficient. He spoke favorably of the operation of ligature of the isthmus of the thyroid in some cases.

On Wednesday morning at 9.30 Dr. Sayre gave a special demonstration of the application of plaster jackets by his method on some living patients. After MacCormac addressed there was a discussion on the treatment of spinal curvatures, introduced by Dr. Sayre.

Speeches by Messrs. Bernard Roth, C. B. Keetley, E.

Freer, and others. Dr. Sayre replied and defended his views. He opposed the application of heavy metal splints and apparatus. He showed a little apparatus, consisting of some vertebræ strung on a wire so as to represent a curved spinal column, and showed that any force applied to the vertebræ, so long as each end of the column remained fixed, merely altered the position of the distortion, but did not remove it, while extension did so at once. He referred to cases in which the application of his apparatus had been followed by immediate benefit, and mentioned a case in which a patient had left the hospital and resumed hard labor soon after treatment by this method. Referring to different apparatuses, he said he had two wagon loads of them at home. He considered plaster superior to felt. Dr. Sayre was very well received, and his remarks greeted with loud applause. Perhaps the largest audience in any section was that which assembled to hear Sir William MacCormac's address, and the subsequent debate on the plaster jacket. Dr. Sayre repeated his demonstration on Friday morning.

Section on Medicine.—In the discussion on albuminuria Dr. George Johnson opened it, and defended his theory. He considered the limited area of the changes in the walls of the arteries was an objection to the theory of morbid blood. Speaking more particularly as to treatment, he said exclusive milk diet was often good in recent cases. He had known a patient of robust frame subsist for years on about a gallon of skimmed milk daily, and nothing else, except when travelling and unable to obtain the milk. He demonstrated the picric-acid tests for sugar and albumen, seven grains in one ounce of boiling water gave a saturated solution. He said in testing by this method never omit to boil, because picric acid may precipitate urates, which are dissolved on the application of heat. He said he considered the only test for albumen equal to the picric-acid tests was the potassio-mercuric iodide test with citric acid, and this was complicated. He then demonstrated the picric acid test for sugar.

One of the secretaries then read a letter on the subject from Sir Andrew Clark, Bart., who said that there was a non-renal form of albuminuria which it was important to distinguish from renal. He said this was sometimes met with for a few days before and after each menstrual period; also from albumen from vaginal and other secretions, bladder tumors, etc., in women addicted to impure habits. He spoke of functional albuminuria, and described four forms, viz.: nervous and oxaluric, mostly in the young; hepatic and gouty, mostly in the old. These were worthy of especial study. He said he had known albuminuria come on after a competitive examination in three out of twenty candidates. He had known temporary albuminuria in a gouty man after attending a public meeting. He remarked that oxaluria, high tension in the blood-vessels, and excess of urea, were followed mostly before long by albuminuria. He spoke of the importance of study of the causes.

On Thursday afternoon a discussion took place on the "Causes of Phthisis," introduced by Dr. Douglas Powell, of London, who said that he doubted much the contagiousness of phthisis. He remarked that many so-called cases of contagion were very strange. A phthisical man marries three wives, who all die of the disease, while he continues to live. How is it that while evolving sufficient of the poison to kill all three wives, it is not present in his body in sufficient intensity to kill him? He considered that it often began with inflammation at the apex of one lung. He remarked that if we could cremate all the bacilli we should still have phthisis left, and other bacilli would be evolved in time.

Dr. Ward Cousins, of Portsmouth, made a very spirited and energetic speech. He said he did not believe in antiseptic inhalations destroying the bacilli. We could not use sufficiently powerful antiseptics to destroy bacilli embedded in the substance of the lung. He protested against covering up the mouth and nose with inhalers to keep out the bacilli which were in the atmosphere. What was the use of that when they were already in the lung? He remarked that the lower classes were particularly averse to a breath of fresh air coming near them, especially such as were suffering from chest diseases. The theory of Koch had given an immense impetus to the practice of antiseptic inhalations. Dr. Cousins employs inhalations in many cases of chest disease, but he advocated open inhalation. He remarked that he believed that free expectoration was very desirable in cases of phthisis. Referring to the late Dr. Ramadge, he said Dr. Ramadge was laughed at in his day. Dr. Ramadge invented a whistle for his patients to use. But Dr. R. was quite right in his theory. It was of the utmost importance to keep at work, and inflated with air, that portion of the lung which was not yet attacked by the disease. Dr. Cousins referred to different inhalers, and after speaking of some which were heavy, said one had been brought out which only weighed three drachms. He then showed his own, which he said only weighed one drachm twelve grains. He had nasal inhalers to wear on either nostril, changing from one to the other when you pleased. He had also a little inhaler for the mouth, to hold in either corner, and remarked that you could go on talking with it in. He created great amusement by continuing his speech with the oral inhaler first in one corner of his mouth and then in the other.

Professor Gairdner of Edinburgh referred to the views of Dr. MacCormac, of Belfast, who held that the cause of phthisis was breathing and rebreathing the same air. He could not subscribe to Dr. MacCormac's views in their entirety, nor could any one, he thought, in the present state of pathology. He could not believe that rebreathed air in itself produced phthisis. He referred to miners' lung and other conditions caused by air laden with foreign matter—these were not phthisis. He, however, believed impure air to be an important condition in the causation of phthisis, even more so than exposure to cold, wind, or damp. He supported Koch in his views. He also believed in the transmission of phthisis hereditarily, but he did not see how this could take place by means of bacilli. He could not conceive of bacilli being given off in the semen or finding their way into the ovum.

In the Section on Public Health, on Wednesday, Dr. Barthe de Standfort, of Dax, read a paper in French, on the "Disinfection of Ships after Infective Diseases," in which he maintained it was impossible to thoroughly disinfect a vessel in the number of days allowed for quarantine. He believed the best disinfectant to be sulphurous acid, which had been recommended to the United States Government, but not adopted on account of its cost. He held that an infected vessel should be thoroughly washed, then fumigated for twenty-four hours, and afterward subjected to very complete ventilation for four or five days.

He was well received, and at a later stage warmly thanked his audience, and said he should carry back to France a lively recollection of his kindly reception in Belfast.

Mr. Kirker, R.N., read a paper on "The Cholera Epidemic in Egypt, 1883," in which he said there were only 8 victims in Port Said, a filthy town of 17,000 inhabitants, and thought that Koch had not sufficient warrant for predicting that the disease would spread from Toulon all over Europe. He believed that the British Isles would this year escape, chiefly on account of recent changes in the weather, with its rain and brisk breezes. He regarded a hot, stifling, stagnant condition of the air as the great danger, but while purifying winds lasted he would say, "Fear not the cholera of Toulon and Marseilles." It was more important to find out the conditions of life of the individual in his home than to look for germs.

Dr. Cullimore, of London, in a paper on "Quarantine," said that people would prefer the risk of cholera

to the rigid application of quarantine, which was not likely to be carried out successfully for any length of time. Quarantine by sea could be defended by arguments inapplicable to sanitary cordons and other attempts at isolation on land. A well-managed ship at sea lying off a port afforded the opportunity of stamping out a disease which was never offered on land.

Dr. Davies, Medical Officer of Health for Bristol, condemned compulsory notification, which he found quite unnecessary in his district of 220,000 inhabitants. He had seen as much cholera as most practitioners for in the first epidemic 2,000 died in Bristol. When threatened they put their drains under disinfection with large quantities of sulphate of iron. Ships were entering the port from Marseilles and cases might be brought in, but he defied them to spread. He did not much believe in gaseous disinfectants.

Dr. Cameron, M.P., Medical Officer of Health for Dublin, and President of the Section, said he did not believe in land quarantine, but he did in a well-established naval quarantine. He was in favor of washing the interior of infected dwellings with soap and water. He found dry chlorine and sulphurous acid would not kill bacteria but solutions would.

Dr. Grimshaw, Registrar-General for Ireland, spoke in favor of the notification of diseases, and though the results had not up to the present time been favorable, he thought that was because the notification had only been carried out partially. To be effective it would require to be reciprocal between the various districts, and even through the country at large.

THE MUSEUM.

The annual exhibition of objects of interest in connection with medicine, surgery, and the allied sciences, took place in the Exhibition Hall, Botanic Gardens, and in the Queen's College. *Subsection A.*—1. Preparations, diagrams, casts and models of anatomical and pathological objects, microscopes and microscopic preparations. *Subsection B.*—2. Surgical and medical instruments and appliances, thermometers, and other instruments for scientific investigation. *Subsection C.*—3. Foods, drugs, chemicals, and pharmaceutical preparations. *Literary and Sanitary Subsection D.*—4. New medical books. 5. Ambulances, carriages, and other means of locomotion for the use of medical practitioners. 6. Sanitary appliances, including drawings, models, and apparatus, illustrative of the ventilation of hospitals, public buildings, and private dwellings. 7. Plans and models of hospitals, public buildings, and private dwellings, constructed upon the most improved hygienic principles. 8. Recent improvements in hospital furniture.

In the Pathological Section I noticed more particularly the following among many other objects. Sketch of elephantiasis labii and plaster cast of the tumor—removed by Mr. Fagan, of Belfast. Specimen of male generative organs, showing operation of cleft urethra as practised among the aborigines of West Australia—Dr. W. Whitle, Belfast. Ruptured intestine caused by crush without external injury—Dr. James Barrow, Belfast. Recent Colles' fracture, third day—Dr. James Barrow, Belfast. Several specimens (about forty) of Colles' fracture—from Queen's College Museum. Bread-cart fracture of tibia and fibula—Dr. James Barrow, Belfast. Colored drawings of skin diseases—Dr. C. F. Moore, Dublin. Ten jelly preparations of eyes, showing various diseased conditions—Mr. Juler, London. Thirty eye preparations—Mr. A. Hill Griffiths, Manchester.

In the Surgical Instrument Department there were exhibits by many of the leading firms. Messrs. Steel & Sons, of Belfast, showed specimens of surgical and other instruments plated by them. Dr. C. Godson exhibited a thermostatic nurse for the bringing up of prematurely born infants, and a four-bladed perforator. He gave a demonstration (on the fœtus) of the latter on Friday, August 1st. Messrs. Wilson & Son, of Harrogate, exhibited Dr. Oliver's urinary test-papers. Among them was a new cupric test-paper for sugar. A paper is boiled in a drachm of water for a few seconds, then removed, the solution reboiled, and one drop of the suspected sugar added, when, if any be present a yellowish opacity appears throughout the fluid.

SPECIAL MEETINGS.

Medical Sickness, Annuity, and Life Assurance Society.—The First Annual Meeting of the Medical Sickness, Annuity, and Life Assurance Society was held in the Greek Lecture Room, Queen's College, on Thursday, July 31st, at 12.30 in the afternoon.

New Sydenham Society.—The Annual Meeting of the Society was held on Thursday, July 31st, at 9.30 o'clock, in the Greek Lecture Room, Queen's College—Sir W. MacCormac in the Chair.

Poor Law Medical Officers' Association.—The Annual Meeting of the Association was held on Wednesday, July 30th, in the Greek Lecture Room, at 1 o'clock in the afternoon. Dr. Joseph Rogers, of London, Chairman of Council, presided.

Irish Graduates' Association.—The Annual Meeting of the Association was held on Wednesday, July 30th, at 5 P.M., in the Library, Queen's College. The President of the Irish Graduates' Association, Professor G. F. Yeo, M.D., was in the Chair.

Meeting of Members of the Royal College of Surgeons.—A Meeting of Members of the Royal College of Surgeons was held in the Greek Lecture Room, on Thursday, July 31st, at 5 o'clock in the afternoon.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HOLIDAY SEASON AND THE HOSPITALS—CHOLERA AND PRECAUTIONS AGAINST IT—OUTBREAKS OF ENGLISH CHOLERA—THE VOLUNTEER AMBULANCE CORPS.

LONDON, August 9, 1884.

THE holiday season may be said to have fairly set in, and although Parliament is still sitting, both doctors and their patients are running off to the country wholesale. At many of the hospitals a large proportion of the staff have gone off for their holiday, and left the bulk of the work to be done by a few of their junior colleagues. At the larger hospitals August and September are not by any means the worst months to see hospital practice. It is true that then most of the ornamental members of the staff are away, but so are the great majority of the students, and cases can be examined at leisure without the overcrowding met with during the session.

No case of Asiatic cholera has yet occurred in Great Britain, although several false alarms have been raised. Any ships arriving from which there has been any reason to dread infection have been promptly disinfected. The Metropolitan Board of Works are taking measures to deodorize the sewage of London at a daily cost of between seven and eight hundred pounds. I understand that at present about thirty tons a day of chloride of lime are being used, and three or four tons of permanganate of potash. The College of Physicians has issued a paper of directions as to precautions to be taken against the cholera.

Several outbreaks have occurred of so-called English cholera in different parts of the country, and some deaths are reported. A deficiency in the water-supply is alleged to be the cause. This has doubtless led to the use of impure water.

The Volunteer Ambulance Corps got up amongst the students of the London hospitals has already attained some success. I believe nearly every one of the eleven medical schools in London has now its own corps. Charing Cross Hospital contributes perhaps the largest number, although having by no means the largest number of students. This is explained when I state that the

movement was started largely through the efforts of Mr. Cautlie, one of the surgeons to that institution. The total number of members enrolled now reaches nearly two hundred. I am afraid that many of them have not as yet learned to observe due discipline, as I have been informed by a member that, at some of the parades which have taken place, about half of those in the ranks were talking and laughing. In the corps of some hospitals too large a number of officers have been appointed, so that at some drills more officers than men have made their appearance.

One must not, however, be too captious, especially considering that it is volunteer work, and work, too, rather outside the area of ordinary medical studies. It is quite as laborious as cricket or foot-ball, but probably not so enjoyable. Lifting about heavy men and manœuvring with heavy stretchers, is by no means play in the hot weather we have lately had. Four bearers carry each stretcher, but one of the movements in the drill consists in transferring the whole weight to the shoulders of one bearer, leaving the other three free.

The utility of the organization will, it is thought, mainly consist in the fact that, when its present members have gone through their hospital career and are scattered all over the country, each of them will, so to say, form a centre whence a similar movement can originate. In remote country districts each medical man who has been a member of the Volunteer Ambulance Corps will be competent to start a local corps, drill and train it. The advantage this will be, should we ever be at war, is obvious.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 10 *to August* 16, 1884.

BARTHOLF, J. H., Captain and Assistant Surgeon. Relieved from duty at Vancouver Barracks, Wash. Terr., and ordered to take station at Portland, Ore. S. O. 114, par. 1, Headquarters Department of Colorado, August 1, 1884.

HEIZMANN, C. L., Captain and Assistant Surgeon. Ordered to proceed to Fort Ontario, N. Y., and report for duty. S. O. 163, par. 3, Headquarters Department of the East, August 13, 1884.

KANE, JOHN J., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 160, par. 1, Headquarters Department of the East, August 10, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending August 16, 1884.

BOGERT, E., Medical Inspector. To be Fleet Surgeon, Asiatic Squadron.

BABIN, H. J., Surgeon. Detached from U. S. S. Minnesota. Ordered to Marine Rendezvous, New York.

WHITING, R., Passed Assistant Surgeon. Detached from Marine Rendezvous, New York. Ordered to Naval Academy, as Member of Examining Board

COOKE, G. H., Surgeon. Ordered to Naval Academy, as Member of Examining Board.

RIXEY, P. M., Passed Assistant Surgeon. Detached from special duty at Washington. Ordered to U. S. S. Lancaster.

WOOLVERTON, T., Surgeon, Ordered to U. S. S. Minnesota.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 16, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
August 9, 1884	0	26	35	3	76	28	0	0
August 16, 1884	2	30	34	2	52	24	0	0
Deaths.								
August 9, 1884	0	7	7	3	20	12	0	0
August 16, 1884	0	3	2	2	7	12	0	0

GUM AMMONIAC contains a small amount of volatile oil which is somewhat irritating to the skin and mucous membranes, and is eliminated through the bronchial and perhaps the mucous membranes. It is chiefly used in chronic bronchitis and bronchorrhœa, but is far more useful in mucous and torpid conditions of the stomach and bowels and perhaps urethra. A pill with one or two grains of aloes and the same of ammonia is often better than the aloes and myrrh pill. Some attribute virtues to it in cirrhosis of the liver and other organs, but muriate of ammonia is better.

HYDROCHLORIC ETHER, or chloride of ethyl, or muriatic ether, is almost identical in its effect with sulphuric ether. But it is so volatile and inflammable as to be almost unmanageable in practice. It is sometimes put in Hoffmann's anodyne as an agreeable substitute for sulphuric ether. Hydrochloric or muriatic ether is used in medicine in solution, and is formed in the muriate tincture of iron, where it is highly prized, and to which more could be added to great advantage.

HYDROBROMIC ETHER is obtained from bromine and alcohol in the presence of phosphorus. It is colorless, volatile, has a very strong ethereal odor, and a warm, sweetish taste. It burns with difficulty and is sparingly soluble in water, but is soluble in alcohol and ether. It has the same effects as hydrochloric ether, and produces anæsthesia without excitement or suffering. It has been inhaled for sleeplessness. It may be used in place of hydriodic ether.

TO OBTAIN HYDRIODIC ETHER, distill absolute alcohol and hydriodic acid together, or alcohol, phosphorus, and iodine. It is non-inflammable, but has a peculiar penetrating, powerful ethereal odor. It is nearly insoluble in water, but soluble in alcohol. Exposed to air and light it liberates iodine. Dose: ten or fifteen drops inhaled several times a day from a handkerchief to bring the system rapidly under the influence of iodine in chronic bronchitis and consumption, but more especially in leucocythæmia, pernicious anæmia, enlargement of the liver and spleen.

ACETIC ETHER is made from acetate of sodium, 8 parts; rectified spirits, 5 parts, and sulphuric acid, 10 parts; distilled together. Sulphuric acid is first formed. It is colorless, limpid, and volatile, having an agreeable refreshing ethereal odor, and is less inflammable than sulphuric ether. It dissolves in all proportions in alcohol and ether, also in eleven or twelve parts of water. It dissolves a little phosphorus and sulphur. When inhaled it produces perfect unconsciousness, without as much previous struggling as sulphuric ether, and is less volatile. From its pungency and agreeable odor, its stimulant and anti-spasmodic qualities, it is used for several of the

minor purposes of sulphuric ether, especially in syncope and in nervous agitation. Dose, 30 minims, properly diluted. Externally, it may be applied wherever sulphuric ether is appropriate. Its agreeable smell and almost equally powerful action renders it a good substitute for sulphuric ether in Hoffmann's anodyne, in the treatment of flatus and gastralgia, but especially in nervous or hysterical sick-headache. It is also used in minor operations where only the first stages of ether action are required.

Formic Ether was discovered by Bucholz in 1782. It is made from 8 parts formate of soda, 7 parts alcohol, and 11 parts sulphuric acid, which are distilled together. It has a strong agreeable odor, like peach kernels, but a pungent taste. It dissolves in nine parts of water and in alcohol. It readily undergoes decomposition into alcohol and alkaline formiates through the alkali of the blood. It lowers the temperature 3½° C., and induces signs of asphyxia, but not so markedly as chloroform; also muscular relaxation and anæsthesia for several hours; 1 or 2 c.c. and 4 to 6 c.c. in dogs, cause less asphyxia, but more somnolence and lowering of temperature, without complete abolition of sensibility, 6 or 8 grains causes only drowsiness in man; it gets into the urine. Formic and acetic ethers are largely used in combination with other compounds of methyl, ethyl, and amyl, in the manufacture of *fruit* essences, which, with the exception of the essence of orange, are rarely, if ever, made from the fruits after which they are named. But the addition of formic ether to sulphuric ether has been suggested, on account of the great reduction of temperature which it causes, for inhalation in surgical operations, which, like ovariotomy, are apt to be followed by extensive inflammation.

Picric Acid, or carb-azotic, is formed by the action of nitric acid on salycin and its derivatives, on phloridzin, indigo, aloes, benzoin, silk, etc. It gives off yellow, suffocating vapors, is acid, and extremely bitter of taste. It is soluble in water, alcohol, and ether, and stains the skin permanently yellow. Its aqueous solution precipitates gelatine. Its salts are mostly yellow, and have a bitter taste. Potassium picrate dissolves in 260 parts of water. Given continuously to rabbits, it causes emaciation, diarrhœa, ecchymosis of the intestines, and yellowness of the conjunctiva and urine. *In large doses* it causes nausea, diarrhœa, and flatulence, with debility, and twitching of the cutaneous muscles. It partially dissolves the blood-disks, and in the white corpuscles the *nuclei* exhibit a lively molecular movement. In man it causes yellowness of the eyes, skin, and urine, and is supposed to illustrate the mode of production of jaundice in certain cases, as in yellow fever and acute yellow atrophy of the liver. It is a supposed remedy for *acholia*, or entire deficiency or suppression of the secretion of bile. Picric acid is trinitophenol, or a trinitophenic acid, and is now generally derived from phenol. Its intensely bitter taste gives it its common name, from pikros, bitter. If heated suddenly, it and its salts explode with violence. It stains animal tissues yellow, and is used by histologists; is largely used in dyeing, and is fraudulently added to beers to make them bitter. It is of value in toxicological analysis, as it antidotes and precipitates alkaloids from their solutions.

Oxalic Acid exists in combination with ammonia, in guano, with calcium in many plants, such as rhubarb, curcuma, ginger, squills, orris, valerian, quassia, and as acid potassium oxalate in phytolucca, belladonna, rumex, and oxalis, most lichens, and many vegetables. Some urinary calculi consist of oxalate of calcium. It is also found in the gall-bladder, in uterine mucus, and in urinary sediments. It is formed by the action of nitric acid on most organic compounds; even sugar, gum, and sawdust yield oxalates when heated with hydrate of potassa or sodium. It is generally made from sugar, molasses, or starch, with nitric acid; one hundred parts of sugar make fifty-eight to sixty of oxalic acid. The dark mother liquids left in the preparation of tartaric acid yield it. Treated with glycerine, it is decomposed into carbonic and formic acids. Acid potassium oxalates, called salts of sorrel or salts of lemon, will remove iron stains from paper, linen, and leather, but oxalic acid is generally used. Its taste is intensely sour. Large doses cause vomiting, with burning pain and constriction of the throat and stomach. The vomits are dark-colored, and may contain blood. When the pain is very severe, collapse may ensue, with drowsiness. Sometimes the symptoms are unaccountably long delayed. Some patients may live to the twenty-third day, but death may occur in from three to twenty minutes, or eight hours. Dark discoloration of the œsophagus, stomach, gelatiniform softening of the stomach, and even perforation of it may occur. The blood is said to be universally bright in color. *Antidotes:* Chalk in water, slaked lime, dried whitewash, etc. It is one of the most rapid and unerring of the common poisons, and hence has rarely been used in the treatment of disease. Still it can be as safely handled as arsenic, aconite, or atropine. It has been suggested in an induration of the stomach and sclerosis of other organs, especially of the brain and spine, in which it causes softening. It seems to have a specific action on the lumbar and dorsal spinal cord. In one case there was great weakness and numbness of the legs and back, so that the patient could scarcely stand, much less walk. In another case the first thing complained of was acute pain in the back, gradually extending down the thighs, occasioning ere long great torture. In a third case the patient complained more of the pain shooting down from the loins to the thighs and legs, than of the pain in the belly. In a fourth case there was numbness, tingling, and pricking in the back and thighs. In a fifth case, there was almost complete loss of power and motion in the legs, which did not pass off for fifteen days. It evidently must be suited to diseases of the spinal cord, opposite, or very different from those which it produces. The only preparations which are used are the oxalates of cerium and iron. The former sometimes controls vomiting, due to reflex irritation from pregnancy, nervous and uterine derangements. It is very insoluble, and hence often inert, and has been given in doses of from 1 to 8 grains three or four times a day. The oxalate of iron is also comparatively insoluble, and hence nearly inert.

Hydrobromate of Quinine consists of potassii bromidii. gr. 162; acid. tartaric., gr. 198; quiniæ sulph., gr. 60; aquæ, ℥ iij. Filter. Dose, 30 to 60 minims. For hypodermic injections and for intermittents with congestion of the brain or spleen.

Hydrobromic Acid has an agreeable, acidulous taste, and most of the physiological and therapeutical actions of the bromides, while it is far less apt to cause *acne*. It is also a corrigent to iron, and prevents the headache so often accompanying its full action and that of quinine. Added to a mixture of quinine and water, it will make a clear solution in the proportion of two minims to each grain of quinine. Added to aconite, it is one of the most soothing and efficacious remedies in fevers and inflammations attended with great nervousness, restlessness, even delirium. It is said not to be useful in epilepsy. Dose of the dilute acid, 30 to 60 minims, largely diluted in water.

Normal Valerianic Acid is a butylformic acid, obtained by the oxidation of normal amylic alcohol; it is an oily liquid, and has an odor resembling that of butyric acid. Ordinary valerianic acid is delphinic acid, discovered by Chevreul in 1817 in the oil of the porpoise (*Delphinum phocena*), and subsequently in the valerian and angelica roots. It is also formed during putrid fermentation or oxidation of albuminoid substances, and occurs in the urine and fæces in typhus fever, variola, and acute atrophy of the liver. It is an oily, colorless liquid, with a penetrating odor, like a mixture of valerian and old cheese, and sharp acrid taste. It dissolves in thirty parts of water, and in alcohol and ether in all pro-

portions. It is a little remarkable for dissolving phosphorus. It is found in the flowers of Anthemis nobilis, or chamomile, and wormwood, but is prepared almost exclusively by oxidizing amylic alcohol with bichromate of potash and sulphuric acid. Given with water it is less disagreeable, and leaves a sweet after-taste. Valerianic acid bears the same relation to amylic alcohol that acetic acid does to ordinary alcohol. Its neutral salts are inodorous when dry, and may be given in wafers. Apple-oil, from applejack, is amyl valerianate. It coagulates albumen, serum, milk, and is slightly irritating to the skin. Its odor is not imparted to urine and blood, but may be perceived in the peritoneal cavity, which renders it useful in some peritoneal diseases, especially false peritonitis. It quickens the heart's action and respiration, then produces debility. In rapid death from it the gastric mucous membrane is pale, hence it produces paralysis or collapse of it. Valerianic acid is not used alone in medicine, and its combinations are useless except the valerianate of ammonia. Angelica archangelica is rarely used in this country, but it is far more agreeable, and quite as efficacious. Valerian contains one or two per cent. of an essential oil, the dose of which is two to eight minims, and is said to reduce the reflex excitability, motility, and sensibility, and even to antagonize the tetanizing action of brucia. The chief use of valerian is in the treatment of nervousness, hysteria, and hysterical disorders generally. There is no doubt as to its great value in these cases. In epilepsy, chorea, and paralysis agitans valerianic acid is to be preferred. The elixir of the valerianate of ammonia is not nearly as useful as the tincture, solid or fluid extract, or the oil, or acid. It has not yet been used in combination with phosphorus or camphor.

Cancer Statistics in England.—At the Cancer Hospital, Brompton, 1,974 cases of true cancer were treated either as out-patients or in the wards. Of these 841 were cases of epithelial cancer, 438 occurring in males, 403 in females; 1,069 were registered as "scirrhus," 54 in males, 1,015 in females; 64 were registered as "soft or medullary cancer," 18 in males, 46 in females. Cases described as "osteoid" and "colloid" are not included in the above computation. The following statistical statements regarding the above cases of scirrhous and epithelial cancer have been prepared at the hospital: Average duration of disease previous to coming to hospital: scirrhus, 15.23 months; epithelial, 20.5 months. Had relations previously affected with cancer, 81. Average age when attacked: scirrhus, 48 years; epithelial, 51 years. Had been previously operated on: scirrhus, 138; epithelial, 102. Average lapse of time before disease returned: scirrhus, 21 months; epithelial, 20 months. Cases ascribed to blow or injury: scirrhus, 60; epithelial, 18.—*British Medical Journal.*

The Treatment of Dysentery with Corrosive Sublimate and Colocynth.—Dr. S. B. Childs, of Brooklyn, writes: "The methods ordinarily advocated for the treatment of dysentery being generally unsatisfactory, and for the reason, to my mind, of being irrational, I would fain bring before the medical profession a mode of treatment that at my hands has produced desirable results. Pathologically considered, we have in dysentery a localized inflammation, either catarrhal or fibrinous, of the mucous and submucous membrane of the lower intestinal tract. That one case may be wholly catarrhal, another case wholly fibrinous, or that the catarrhal may run into fibrinous, has been amply proven. With any of these conditions present the majority of medical writers still advocate sugar of lead, opium, etc., *ad nauseam.* Hardly a mixture is given that does not contain more or less opium. Now, paralyzing the contractility of the intestinal walls by this nervous sedative certainly does not cure. Castor-oil and Epsom salt have been recommended, but generally in too large doses, and then withal they invariably have as an adjunct some preparation of opium. Having an inflammation of a severe type, it would seem a *desideratum* to give some form of medicine that would produce an alterative action directly in the tissues involved, and yet at the same time not to excite any disturbing influence on the system at large. Now, we have in small doses of bichloride of mercury just what will answer this requirement. The griping pains and tenesmus that are so distressing in this complaint can be readily controlled by tincture of colocynth in minute doses. My mode of procedure is to give the mercury alternately with the colocynth, and on the pain being relieved to supersede the colocynth with the tincture of ipecac." Dr. Childs then gives notes of two cases illustrating the efficacy of his treatment. In the early acute stage he gave tincture colocynth in gtt. $\frac{1}{10}$ doses, alternating every half hour with corrosive sublimate, gr. $\frac{1}{100}$.

Musk.—Although musk has been long well known in the West, yet, says Dr. Macgowan in his report on the health of Wenchow ("Imperial Maritime Customs"), it seems worth while to translate what Chinese writers have to say about it. The musk-deer is found throughout the mountains of Yünnan, Szechwan, and Thibet; it is a timid little animal, and often dies of fright. It feeds on juniper-leaves and reptiles; snake-bones are found in its stomach. In spring its glandular pouch is greatly swollen and inflamed. The secretion is discharged with the urine. Musk-deer always resort to the same place for micturition, and cover their urine with earth. In such places deposits of a superior quality are found, amounting sometimes to fifteen catties (a catty is a Chinese weight of about one and one-third pound). The article which is most prized is that which falls from the musk-deer on to the ground, and is gathered in grains that are as precious as pearls. These deposits are so pungent that, if carried through a garden or woods, it prevents fructification. The poisonous effect of fresh musk on vegetation is shown also by the blighted appearance of places which the musk-deer selects for its convenience. For some distance around these places there is an absence of plants, and farther off the leaves exhibit a yellow tinge. This valuable substance no sooner leaves the hunter's hands than skilful manipulators adulterate the article for wholesale dealers, who further adulterate it for the trade, by which time it contains only about ten per cent. of genuine musk. Musk is said to be an anthelmintic, and to cure the bites of venomous serpents.—*Lancet.*

Mr. Lawson Tait on Pneumonotomy.—Mr. Lawson Tait has written to the *British Medical Journal* the following letter, which we believe most persons will agree is an eminently sensible view of the case: "Sir: I think the facts that the idea of the application of surgery to the diseases of the lungs occurred to Sir Spencer Wells forty years ago, and to others before him; that all of us engaged in the surgery of the abdomen must have, as I have often done, restlessly discussed the possibility of passing above the diaphragm; and yet that nothing has been done, form a sufficiently trenchant statement of the case. Nothing has been done beyond the drainage of old suppurating pleurisies, and possibly a few gangrenous vomicæ; and I do not think it is likely that we shall go much beyond this, in spite of Dr. Biondi's experiments. I have had several cases of thoracic disease sent to me, with the tempting request that I should attempt an operation; but I have never seen my way to the effort, they were all so clearly cases of malignant disease. I cannot imagine that any man in his senses would attempt to remove a human lung with a tumor in it. It would not be resection of parts of four ribs which would permit the removal of a tumor sufficiently large to admit of accurate diagnosis; and I cannot observe, in the literature just at the moment accessible, that any other kinds of tumors occur in the lung, save those of hydatid origin, and those of a cancerous nature. If the tumor were hydatid, the removal of the lung would be unnecessary. If the tumor proved to be an aneurism, the disaster would be awful.

For phthisis, I imagine removal of the lung would be a still more absurd proposal. If one lung were riddled with vomicæ, the chances of the other lung being affected would amount to certainty. If there were only one large cavity, not of tubercular origin, or very chronic in its history, drainage would suffice. The facility with which Dr. Biondi has removed lungs, and parts of lungs, from dogs, guinea-pigs, cats, fowls, pigeons, and sheep, and the absence of mortality from such operations, is likely to be a snare rather than a help. It does not need saying that the removal of a healthy lung, collapsed by the introduction of air into the pleura, would be a very easy matter, and very different from the removal of a diseased and adherent organ. There would be as much difference as there is between normal ovariotomy and removal of a pyosalpinx. It is perfectly clear that these animals, with their deep and narrow chests, differ very much from us, with our wide and shallow cavities, in their powers of enduring the accident of acute pneumothorax; certainly they would differ from us immensely in the facility with which pneumonotomy may be performed. Their chests are built for the endurance of the special efforts of great speed, and we have lost those physical characters; and I venture to say that, if acute pneumothorax were suddenly inflicted upon sixty-three healthy adult human beings, death would be the immediate result in the great majority of the experiments. The analogy between nephrectomy and pneumonotomy, of which Sir Spencer Wells makes use, is also a misleading one; for the functions of the kidney may be interfered with to a considerable extent, and even entirely for a considerable period, without apparent trouble; but we have no proof that this is probable in the case of the lung. The only experiment I ever saw in this direction, the result of an accident, resulted in immediate death. I do not think the severest critic can say of me that I have any tendency to obstruct surgical progress; but it seems to me that neither *à priori* reasoning, nor clinical experience, will lead us further than we have got in pulmonary surgery—drainage, with the useful addition of costal resection in old-standing empyema; and I am quite sure that we may regard Dr. Biondi's experiments as the outcome of the work of an enthusiast, misleading in their tendency, and dangerous for any practicable application which might be made of them.—I am, etc., LAWSON TAIT."

THE HISTORY OF THE DISCOVERY OF THE CIRCULATION, recapitulated, divides itself naturally into a series of epoch-making periods: 1. The structure and functions of the valves of the heart, Erasistratus, B.C. 304. 2. The arteries carry blood during life, not air, Galen, A.D. 165. 3. The pulmonary circulation, Servetus, 1553. 4. The systemic circulation, Cæsalpinus, 1593. 5. The pulmonic and systemic circulations, Harvey, 1628. 6. The capillaries, Malpighi, 1661.—*Dr. Henry C. Chapman.*

PERFORATING GUNSHOT WOUND OF THE STOMACH AND LIVER.—Dr. R. M. Stone, of Omaha, Neb., sends us the following: "I was called on May 20th, 1884, to see Mike P——, who 'was shot in the bowels.' I found a young man of twenty-four, hearty and vigorous in appearance, lying in a state of unconsciousness, with a bullet wound of entrance, badly powder-burned, beneath the margin of the left tenth rib and three inches from the median line, and a wound of exit over the right tenth rib. The patient's pulse was good, and though he was suffering from shock yet there was no evidence of collapse from serious internal hemorrhage. I had determined on my way out to the case to perform laparotomy if there was evidence of serious internal hemorrhage, but finding no evidence of such condition, and no definite evidence of perforation of the stomach, I determined to treat the case expectantly, but saw no reason to hope for favorable results. Dr. James Carter saw the case with me in the evening, and agreed with me in the very unfavorable prognosis. The patient died nineteen hours after receiving the wound, and at my request Dr. M. A. Robert made the autopsy. We found that the abdominal cavity was partially filled with bloody fluid, consisting largely of lemonade, which had escaped from the stomach. The ball, a 44-calibre, had wounded the omentum, entered the stomach along the greater curvature, emerged one-half an inch from its entrance, then entered the liver just above the gall-cyst, ploughed its way through two and a half inches of the liver, and then entered the right abdominal wall, fracturing the tenth rib and emerged over it. The autopsy demonstrated that a laparotomy could not have been useful, for, though the wounds of the stomach could easily have been sewed up, yet the lesion of the liver and the violent peritonitis that must have ensued, together with shock, would have proved fatal."

EXTRA-UTERINE PREGNANCY ENDING IN SUPPURATING CYST OF TEN YEARS' STANDING—PERITONITIS—AUTOPSY.—Dr. G. C. Park, of Murraysville, Pa., writes: "It may be of interest to the readers of THE MEDICAL RECORD to recite through the columns of your journal a brief history of the case of the wife of Dr. W. J. R——, of Newlonsbury, Pa. She became pregnant for the first time in December, 1873, and after a protracted labor of five days was delivered by instruments on September 14, 1874. She made a good recovery, being able to attend to her ordinary household duties, and only complained of slight pain below the umbilicus and to the left of the median line about April, 1875. She continued to perform the duties of a mother and housewife, though there was slight tumefaction near the sigmoid flexure of the colon; and in May or June of the same year (1875) she passed, by the bowels, a quantity of pus, estimated by her husband at from a pint to a quart. In 1878, she passed a quantity of hair by the bowels. In 1882 she passed a large quantity of pus with a roll of hair estimated at from three to four inches in length, and one line in thickness. On May 11, 1884, seven weeks after her eighth labor, one of which was a premature, and while dressing her hair, she was suddenly seized with a pain below, and to the left of the umbilicus, accompanied by chilly sensations, but no rigor. Symptoms of diffused peritonitis were soon manifest. On May 19th she died, aged thirty-four years and thirteen days. By her own request we were permitted to have an autopsy, which, with the assistance of Dr. Ewing, I conducted. On opening the abdominal cavity pus oozed out, which was preserved and estimated at a quart. The bowels were all glued together by recent adhesions. Pus extended from the bladder to the diaphragm. The left lung was adherent to the posterior thoracic wall. Attached to the sigmoid flexure of the colon was a tumor not much larger than an ordinary-sized hen's egg. This was divided and revealed three teeth, one very large and the shape of the canine of the adult. Coarse dark hair lined the sac containing the teeth. A mass weighing about a pound was found beneath the fœtal tumor, placental-like in consistency, ragged and highly vascular. The right ovary showed a small ovarian tumor and was itself hypertrophied. The strange features of the case are these: 1, her health was good during all this time; 2, the long time and no interference with pregnancy and delivery; 3, pus formed and escaped by the bowels without any premonitory symptoms. On May 11th the pus-sac broke, discharging the contents among the bowels, resulting in the death of the poor woman, over whose head the sword of Damocles had been suspended for near ten years."

RECTAL ETHERIZATION.—Dr. S. Baruch, of this city, writes: "Apropos of rectal etherization, I am glad you are giving prominence to the fact that it is dangerous. I was just on the eve of adopting it in an operation for trachelorrhaphy after hearing it highly commended by, and after seeing it act beautifully in the practice of, one of our best surgeons. On my next visit, however, I learned that a patient had died purely from the effect of rectal etherization, the whole intestinal canal having been found hemorrhagic."

ON HAY FEVER AND ROSE COLD.

BY MORELL MACKENZIE, M.D. LOND.,

CONSULTING PHYSICIAN TO THE HOSPITAL FOR DISEASES OF THE THROAT; LECTURER ON DISEASES OF THE THROAT AT THE LONDON HOSPITAL MEDICAL COLLEGE; LATE PHYSICIAN TO THE LONDON HOSPITAL.

IN a lecture on hay fever, delivered not long ago at the London Hospital Medical College (see *British Medical Journal*, May 7, 1884), the present writer alluded to the complaint as one unknown in the "good old times." Now, though, both in letter and spirit, this statement is perfectly correct, it too much ignores the fact that an individual idiosyncrasy rendering people sensitive to the influence of rose pollen was not very uncommon two hundred or three hundred years ago. As the term "rose cold" has survived in America, while it is quite unknown here, I think it probable that the complaint may be much more common on the other side of the Atlantic than it is in England; and it is with the view of eliciting some "modern instances" that I venture to bring under the notice of my fellow-workers in the New World some remarkable examples of rose catarrh as related by writers of the sixteenth and seventeenth centuries.

As early as the year 1565, Botallus[1] (known to fame as the discoverer of the *foramen ovale* in the heart) affirmed that he knew persons who held the smell of roses in deadly hatred, because it gave rise to headache, sneezing, and troublesome itching of the nose. Somewhat later, Van Helmont[2] (1577–1644) mentions the odor of sweet-smelling substances as causing headache, and in some cases difficulty of breathing; he also gives[3] the case of a canon who was *totâ æstate propemodum asthmaticus, totâque hyeme liber*. It must be allowed, however, that this passage, though suggestive, is not quite conclusive as to the nature of the malady. In 1673 I. N. Binningerus[4] says that he has often heard from James à Brun, a professor of the medical faculty in the University of Basle, that his wife, Ursula Falcisin (a lady, as he is careful to inform us, whose charms were of the "too, too solid" kind, *ampli corporis et carnosi*), suffered from coryza for several weeks every year during the rose season.

A few years later we find Ledelius[5] recounting the case of a merchant of Grünberg who could not smell a rose without immediately suffering from itching, followed by inflammation of the eyes, with profuse lachrymation and headache lasting some days. We come next to a case of especial interest, which was published in 1691 by I. Constant de Rebecque.[6] This passage is important as conveying the result of an experienced physician's observation of his own symptoms. He tells us that for thirteen years he had been afflicted with coryza during the rose season, which *per totum tempus quo rosæ se mihi offaciendas præbent durat eoque elapso sponte desinet.*

At first he attributed his sufferings to heat, but in the year 1685, when the summer was exceptionally hot and there were hardly any roses on account of caterpillars, he was struck by the fact that his annual disorder did not trouble him. The symptoms came on at once, however, after inadvertently plucking a rose toward the end of the season. He concludes that something flows from roses (*e rosis aliquid effluere*) which stings the nose (in his case exceptionally sensitive) and *aculeis quibusdam solutionem continui et si non sensibus obviam excitet.* This observer, therefore, came very near the mark as to the real cause of the disease, to which he applied the term *coryza a rosarum odore.*

An extraordinary case is related by Herlinus[1] (on the authority of Adrian Spigelius, whose name still survives in one of the lobes of the liver) of a Roman cardinal, Oliver Caraffa, who could not bear the smell of roses. This is confirmed from personal knowledge by another writer,[2] who adds that Caraffa was obliged every year to shut himself up during the rose season, guards being stationed at all the gates of the palace to stop any visitor who might be wearing or carrying the dreaded flower. It is, of course, possible that in this case the roses may have produced some other affection than rose fever, but as it is distinctly stated that it was the *smell* to which the cardinal objected, we may, I think, fairly conclude that the "sting of the flesh" which tormented him was, in fact, rose pollen.

About the end of the seventeenth century Riedlin relates the case of a merchant with whom he was acquainted who was afflicted with sneezing and catarrh every year when the roses were in bloom. Riedlin advised his patient to avoid the *cause* of his complaint, a point beyond which we have not even yet advanced.

Heberden's[3] observations make a kind of connecting link between the rose catarrh of the seventeenth century and the hay fever of the nineteenth, for though this physician does not seem to have been at all aware that the complaint had any connection with flowering plants, he mentions casually that five of his patients suffered from catarrh for a month every summer, while another was similarly affected during *the whole of that season.*

The author of this paper will feel greatly indebted to any American physician who may be able to bring under his notice any well-authenticated case of rose cold.

19 HARLEY STREET, LONDON, W.

A MATERNAL IMPRESSION.—Dr. F. W. Epery, of New Richmond, Wis., writes: "A lady in her second pregnancy was much affected and greatly annoyed by a deformed brother-in-law, who spent his whole time in the house and constantly complained about his *imaginary* ills—as he was a confirmed hypochondriac. His deformity consisted in a very pronounced posterior curvature in the upper dorsal and lower cervical vertebra, a long neck approaching the horizontal, with head deficient in occipital region. When the child was born it had precisely the same posterior curvature, and there was a complete arrest of development from the first cervical vertebra to the frontal bone. There was no brain, and the face resembled that of the deformed brother-in-law."

ON SOME DISORDERS OF NUTRITION RELATED WITH AFFECTIONS OF THE NERVOUS SYSTEM.

Being the Address in Medicine Delivered Before the British Medical Association at its Meeting in Belfast, Ireland, July 30, 1884.

By WILLIAM M. ORD, M.D., F.R.C.P.,

ICIAN TO ST. THOMAS'S HOSPITAL, LONDON, ENGLAND.

(Special for The Medical Record.)

(Continued from page 212.)

Muscular wasting coexistent with joint disease.—For some years I have been led to observe, in a certain group of cases of chronic rheumatic arthritis, the coexistence with the joint-lesion, always well marked, of affections of muscles. These have been not merely weakness of extensors, and tonic contraction of flexors, the two factors which largely determine the character of the deformities of the disease, but marked and excessive wasting of muscles, closely resembling those of progressive muscular atrophy. Together with these, I have noted the existence of fibrillar tremors, and of electrical reactions like those of progressive muscular atrophy in the general, but with some indications of less loss of galvanic than of faradic sensibility, with some slight indication of the reaction of degeneration.

In addition to those, I have noticed, as others before me have noticed, a wasting of the tissues other than the muscles of limbs.

These concern, in the hands, loss of substance in the soft parts of the digits, the wasting of the skin, which brings about a satiny or glossy quality of the surface, and a dwindling of the nails, which we see carried to the full in extreme true gouty affection of the fingers, where the nails become small scaly appendages of the carrot-likedigits.

In some cases I have also observed exaggeration of the so-called tendon-reflexes, and in some fibrillar tremors. In fact, as they present themselves to me, these are cases of progressive dystrophy of joints marching with progressive atrophy of muscles, and with atrophy of the other tissues of limbs. My friend, Dr. Hadden, who has taken great interest in these cases, has recently presented a paper to the Clinical Society of London, taking up some of the points here mentioned. I may here relate two cases which bear upon this relation.

M. K——, a married woman, aged sixty, was recently under my care. There was no history of gout or rheumatism in her parents, but she had one sister, who was said to suffer from gout. She presented the lesions of rheumatic arthritis in the hands, knees, and ankles, but the hands were most affected. The muscles of both arms were distinctly wasted; the skin of the ends of the fingers was glossy, and the soft tissues around the two last phalanges were much wasted. The right hand was affected more than the left. The tendon-reflexes were greatly exaggerated, both at wrist and elbow, particularly on the right side. The hands showed the adduction deformity of chronic rheumatic arthritis rather than the claw of progressive muscular atrophy. The electrical reaction, of both kinds, was lessened; she had, therefore, slowly progressing in company, arthritis, wasting of muscles, wasting of tissues generally, and wasting of skin, without the reaction of degeneration. I could, in her case, detect no reflex cause. She was anæmic, but not thin, and had worked hard. The case certainly pointed to a common central nervous origin of all the dystrophies. A case now under care is more interesting.

The patient, a man, following the occupation of salesman, and not the victim of overwork, has been ill for ten or twelve years. He suffered from rickets in childhood; there is no record of acute rheumatism in his own life or of any joint-affection in his ancestry. When first ill, he had occasional attacks of weakness in his limbs, accompanied by swelling in the ankles, knees, wrists, and fingers, never in the shoulders or elbows. These attacks came and went, leaving him, at first, well in the intervals, but for some years he had not been possessed of proper muscular power. Two years ago he was violently shaken by a thunderstorm, since which the symptoms of which he now complains have appeared. He has, now, typical rheumatoid arthritis of the hands and feet; the right shoulder is stiff and painful on movement, particularly in abduction; there is grating; and a rim can be felt around the articular end of the humerus. The elbow is not involved, but the wrist is greatly distorted, almost to dislocation. There is wasting of the interossei of the hand, of the thumb-muscles, of the muscles of the forearm, and in an excessive degree of the right deltoid; the right biceps being also, but not so profoundly, wasted. There is no paresis, only such loss of motor power as would correspond to loss of muscular substance. Marked fibrillar twitchings can be seen in the arms, being more active in the right. The feet show chronic arthritis without any notable wasting of muscles. The knees are slightly affected, the hips free. There is no loss of sensation anywhere, and no impairment of the functions of bladder or of the rectum. The deep reflexes are rather diminished, the superficial not affected. The electrical reactions of the muscles chiefly affected are impaired. The right deltoid is much less sensitive to the galvanic current than it should be, and responds only to a faradic stimulation stronger than that which should normally excite it. The biceps give the same reactions in a lesser degree. The other muscles have normal reactions. In this case there is no history of gout, of lead-poisoning, or of causes likely to give rise to spinal trouble. These dystrophies of muscle and nerve are not accompanied by dystrophies of skin. The joint-affection was, to all appearance, preceded by a distinct accession of muscular debility.

Articular dystrophie brought about by irritation of spinal cord.—If the considerations upon which I have been dwelling indicate the probability that some such influence as is excited by the spinal cord in producing muscular atrophy may produce also articular dystrophy, there are others which bring into stronger relief the influence of the spinal cord in bringing about directly affections of joints independently of muscles. I cull from my note-book a typical case of the kind. A lady, of healthy family and healthy personal antecedents, went, soon after her marriage, to an evening party. For the reception of a large number of guests, a tent was provided. Rain fell heavily all the evening, and saturated the canvas. For certain reasons she did not dance, but sat in the tent for some hours, with her back to the wet walls, experiencing, although not actually in contact with the moisture, a sense of intense chill in the back. Within a day or two arthritis set in in both knees. It was not intense, but presently gave rise to much swelling and deformity. The ankles, hips, elbows, hands, and shoulders were in succession attacked with the same trouble. All the joints were excessively swollen, tender, and painful; but the muscles were not noticeably affected. The joint affection was one of steady progression, not one of paroxysmal exacerbations, followed by increased mischief, and ended by rendering her practically helpless as regarded locomotion, simply by reason of pain. Her muscles retained a fair bulk and strength; the reflexes were exaggerated, but it is necessary to remark that the great sensitiveness of the joints prevented a proper investigation on this point. The electrical reactions were not, I am sorry to say, tested. Her mind remained singularly clear and well balanced; her bodily functions were not affected; she became the mother of several children; and, in spite of locomotive difficulties, manifested an exceptional power in the direction and discipline of her household. All the effects of the long chill received by the spinal cord seemed to fall upon the joints alone, producing, in a typical form, a progressive rheumatic (to use the accepted term) arthritis. After reading M. Charcot's cases, one might be tempted to wonder why such painful

affection of joints should not have been followed by atrophy of muscles. But, as a matter of observation, I think it will generally be found that the influences which give rise to violent reflex reactions are themselves mostly of the lighter kind. Those which are superficial, call out rapid and widespread reaction, as, for instance, an irritating particle in the nose; those which are deep and intense, call out the more concentrated reactions which end in an inflammation, or are proclaimed by severe pain. This is but a parenthesis, but it relates to a point in reflection of irritation which is worthy of deep thought.

Observations of Senator and others on the nervous production of arthritis.—I might illustrate this point more fully from my records of cases, and should do so, were it not that the spinal cord origin of certain kinds of chronic arthritis has been already contended for by other observers. Senator, in his all too short paper on Arthritis Deformans in "Ziemssen's Cyclopædia," speaks thus: "Existing observations seem to point exclusively to the peripheral variety of the disease, as connected with the affections of the nervous system." Remak and Benedikt were probably the first to regard articular affections as a result of irritative states of the spinal marrow and sympathetic. Indeed, Remak went so far as to call arthritis deformans by a new name, "arthritis myelitica" and "myelitico-neurotica."

The date of the publications in which these views were advanced, is as far back as 1863 and 1864. Senator, in his comments on them, after mentioning a case published by Kohts in 1873, in which this disease followed a fright, proceeds to say, "The usually symmetrical order of its invasion (the invasion of arthritis deformans), can hardly be explained, unless we assume the existence of some central causes situated in the nervous system. The disease is often associated with neuralgic and tropho-neurotic symptoms. Finally, some results of treatment, particularly those recorded by Remak and others concerning the effects of electricity directed to the central nervous system, serve likewise to support this view."

That it should be regarded by Senator as difficult to explain the symmetrical order of invasion, except upon the assumption of a central nervous irritation, illustrates in a forcible way the extinction of the beliefs of one generation by the beliefs of its successor. Sir James Paget's "Lectures on Surgical Pathology" are not many years old,—they were published in 1853.

In this most fascinating book, written by a man whom I may fairly call the most accomplished, as, indeed, also the most eloquent man in our profession, we find set forth, in the most convincing way, the argument "that all symmetrical diseases depend on some morbid material in the blood," and that certain blood diseases have "seats of election." The reasoning upon which this is based is found later in the book, where, on pages 24 *et seq.*, Sir James proceeds to develop a principle, the germ of which is in the writings of Treviranus. The sentence of Treviranus is, "that each single part of the body, in respect of its nutrition, stands to the whole body in the relation of an excreted substance." According to the ideas which follow, every part of the body has its special nutritional and excretory endowments, inasmuch as it differs from all other parts, however identical in superficial seeming, in its reaction to alterations of the blood When there is symmetry on either side of the vertical plane, the corresponding parts agree in their reactions, while differing from all others. The second chapter—on the conditions necessary to healthy nutrition—contains a most interesting sketch of the influence of the nervous system on nutrition; but the main ideas of causation are independent of nervous influence, and rest on relations between the blood and the tissues.

The idea of some such special endowment cannot be spoken of without more than respect.

It is held still, in respect of cutaneous diseases, and in respect of gout, and particularly of goutiness. I maintain that it must still be accepted as a truth, but as only a part of the truth, as regards nutrition, and I enter my protest against the short-sightedness which fails to recognize now what Sir James Paget did, in his well-balanced judgment, recognize thirty years ago, the possibility of the combined action of two dissimilar processes.

To resume now the line of thought which has been arrested by this excursion, let us, for a moment, review our position. We have considered possible causation of dystrophies of muscle by irritation of joints, of dystrophies of joints by injuries of bones, of dystrophies of joints by a sort of subjective irritation coming through channels of centripetal muscular nerves, of dystrophies of joints and muscles by irritation or disease of nervous centres.

Digitorum nodi.—Are these all the channels by which nervous influence may affect the nutrition of joints? I think not. For more than fifteen years the probability that the form of chronic rheumatic arthritis, called by Heberden, "digitorum nodi," by Haygarth, "nodosity of the joints;" by Senator and others the polyarticular (I am not responsible for the hybridity of the term)—the polyarticular form of arthritis deformans, is in many cases a dystrophy, determined by nervous irritation propagated from the uterus to the spinal cord, and reflected upon the joints, has presented itself to me. Let me give briefly the notes of a case which I saw first in the year 1868.

The subject was an unmarried lady, twenty-six years of age. She came to me complaining of terrible dysmenorrhœa, and of what she had been taught to call rheumatic gout. She was thin, anæmic, sallow of complexion, had abundant acne on the face, and was hysterical, having given up society and all active occupation for the contemplation of her ailments. There was no small justification for this absorption. Out of every month of her life she had only one week of ease. The menstrual period lasted one week, and was attended with excessive pain in the pelvis and back. A week before its commencement the smaller joints of the extremities became swollen and excessively painful. They remained in this condition till the end of the week following the cessation of the menstrual period. There were some variations in the severity of the dysmenorrhœa, and there were corresponding variations in the intensity of the joint-affection. During the week of ease the joints showed a little deformity, but were freely movable, and free from pain or tenderness. The "rheumatic gout" was the main object of her attention, from its long persistence; and at first I adopted the idea, already adopted by others, that the two troubles were the effect of a common cause, a rheumatic inflammation affecting joints and pelvic organs at one time. Treatment instituted upon this hypothesis failed, had long failed to give any relief, and what may be called the central position of the menstrual trouble, led me to the opinion that it was the primary mischief giving rise, in some way that was then not very clear to me, to arthritis.

The uterine conditions were now steadily attacked. At the end of a twelvemonth's treatment, the dysmenorrhœa was subdued. As it yielded, the joint-trouble dwindled; and, with its cessation, the rheumatic paroxysms disappeared. So did the acne, the unhealthy complexion, and the general ill-health. At the present time, this lady is stout, healthy, and vigorous of mind and of body; but the joints retain some painless deformity. In the year 1869, I published an account of this case, and of others which appeared to me to indicate that uterine irritation, chiefly associated with hyperæmia of the organ, were capable of reflection upon the joints, with the result of inducing a form of rheumatic arthritis. The paper is probably little known to you, and you will pardon me if I present to you some of its matter and conclusions.

Haygarth, writing in the year 1805, on the "Clinical History of the Nodosity of Joints," stated that he had seen thirty-three cases of that condition, all in women. He regarded the affection as peculiar to women, and as

belonging to the climacteric and subsequent periods of their life. Only three out of his thirty-three cases had the "nodes" during the period of regular menstruation. Of these, two appeared to be between thirty and forty years of age; the third had suffered twelve abortions. In all, the fingers were chiefly affected. Haygarth separated this affection as "nodosity of joints" from "rheumatic gout"—a term already in use when he wrote; and he considered it to be chiefly a disease of the middle and higher classes. Curiously enough, when I analyzed my note-book, I found records of just the same number of cases—not of nodosity of joints simply, but of rheumatic arthritis, combined with decided symptoms of uterine disorder or irritation. I excluded from the list cases in which there was evidence of uratic deposits, and cases in which no known uterine complication existed, though both classes demanded separate attention, as forming chapters of the history of arthritis.

Of the thirty-three, twenty-six belonged to the middle and upper classes, mostly to the former, the remaining seven to the poorer classes; seventeen were unmarried, thirteen were married, and three were widows.

As regards age, ten were between twenty and thirty years; eleven were between thirty and forty; nine were between forty and fifty; and three were between fifty and sixty.

The indications of ovario-uterine complication in the several cases comprehended marked irregularity of catamenia in two; catamenial flow simply in excess, one; catamenial flow very scanty in one; catamenia irregular with excess in two; catamenia recently disappeared in four; catamenia recently reappeared after apparent cessation, the reappearance coinciding with arthritic attack, in two; dysmenorrhœa with excess in eight; dysmenorrhœa, with deficiency in four; constitutional symptoms of climacteric present in two; fibroid of the uterus with menorrhagia, but not dysmenorrhœa, in one; catamenia regular, relieving pain present at other times in sacral region, in one; catamenia excessive, with leucorrhœa, in one; profuse leucorrhœa in woman married several years without pregnancy, one; woman married several years without pregnancy, one; case in which arthritis occurred on two occasions a week before parturition, these being the only pregnancies, one; climacteric long past, arthritis began then, and has since continued, one.

In four of the above cases, ovaritis existed; and it is important to notice, first, that amenorrhœa is not noted in any case, second, that the conditions noted are mainly such as would involve hyperæmia of the internal genital organs; third, that marked dysmenorrhœa is noted in twelve or more than a third of the total number.

The seat of arthritis was various. It affected the hands alone in thirteen cases; the hands, wrists, and elbows in three; the upper extremities in one; the right hand only in one; the right hand and wrist in one; the hands and feet in one; the hands, feet, and knees in one; the knees and ankles in one; both extremities in six; both extremities on one side in one; the ankle and tendo Achillis in one. From this, it appeared that the hands were more often affected than any other parts, the metacarpo-phalangeal joints being of all joints the most obnoxious to this form of arthritis. The hands, besides being alone attacked in the cases, shared the affection with other joints, and principally with other joints of the upper extremity, the wrists excepted, in all the rest of the cases, except two. In three of the cases, where the affection was limited to one side of the body, or having begun, continued excessive, on one side, there were ovarian pain and tenderness on the same side, and a distinct frequency of neuralgia on the same side.

An inspection of the cases brought out further most interesting relations. Not only did the arthritis coincide with ovario-uterine affection; but, in a considerable proportion of cases, paroxysms of arthritis coincided with menstrual periods. This sort of parallel march was noted in fourteen cases, in one of which arthritis preceded menstruation as its regular herald; in seven, arthritis regularly accompanied; in two, it followed; in two, it both accompanied and followed; and in two, arthritis occurring in the intervals was relieved by menstruation.

Now, if these had been so many cases of dysmenorrhœa, the occurrence might perhaps have been accepted as an argument for believing the dysmenorrhœa token to be a part of a general rheumatic process. But, though the conjunction was reported in seven, it was conspicuously absent in as many cases; and these are precisely the instances which do most to prove that the arthritis is a product of the uterine hyperæmia. With this simple question, we will deal for a moment, leaving the *modus operandi* to be discussed later on.

Among the seven cases referred to as not accompanied by dysmenorrhœa was that of a lady then fifty-two years of age. She had had a large family—in all twelve—and it was then as much as five years since she first began to suffer from arthritis. Before the arthritis troubled her, she had begun to experience excessive menstrual loss. She consulted for this a distinguished gynæcologist, who found the uterus enormously engorged, but otherwise free from disease. The engorgement was lessened by treatment, but not by any means cured, and the menorrhagia went on. The arthritis first came in the form of sharp inflammation and swelling of the knuckles of both hands, rendering them completely useless. It began usually on the second or third day of the menstrual flow, and continued as long after its cessation. The periods becoming more frequent and lasting longer as time went on, she became reduced to a very pitiable state. She was anæmic, exceedingly feeble, was crippled in hands, wrists, and knees, and lost her rest by reason of what she called "fidgets," uneasy but indefinable sensations in her limbs and abdomen, unaccompanied by pain or spasm.

Change of air and of scene, baths, tonics, alteratives, were all used in addition to local remedies, but no relief was obtained till, as she reached the age of fifty years, the periods began to be less frequent.

At length, intervals of two or three months occurred, and allowed her to gain strength, when she lost her arthritis and her fidgets, and appeared perfectly healthy. Of late, the periods had been still further apart; but still, whenever the catamenia appeared, she was once more crippled.

The association of the arthritis with this painless menorrhagia began clearly at a time when the patient was weakened and drained of blood. The fidgets illustrated the irritability of the spinal cord related with imperfect nutrition, and the arthritis came out as a resultant of two conditions—uterine irritation and spinal sensitiveness.

I may add that I have seen this lady within the last few weeks, not as a patient; that the catamenia have entirely ceased for three years; that she has had no joint-trouble since, excepting on one occasion, when it occurred in conjunction with severe intestinal catarrh; and that she is now ruddy, well nourished, active, and cheerful.

A lady, aged fifty-one, the mother of six children, came to me in 1882 with a gouty-looking inflammation in the elbows, wrists, hands, and knees. This had occurred a day after the return of the catamenia, previously absent for twelve months. She had no signs of gout in the shape of deposits, and her own expression was, that she felt the attack to be really "in the nerves." The period was short, and the arthritis disappeared. But the catamenia having since returned with unusual freedom and duration on two occasions, she had each time had the arthritis severely enough to cripple her. The arthritis came on at the end of the periods, the last of which was accompanied by abdominal pain, a circumstance hitherto unknown to her. I am now able to report of this case that the catamenia have ceased, and that the joint-affection is forgotten.

I might multiply my citation to a large extent, for the relation is illustrated constantly now that it has once been recognized.

Hypothesis of reflex causation of arthritis by uterine irritation.—The argument which was founded upon these cases and others not now quoted, had the following general bearing: that, seeing this frequent coexistence of a certain kind of inflammation of the joints with uterine hyperæmia, seeing also that the joint-inflammation increased in intensity in a very marked proportion to increase of the uterine hyperæmia, and that, also, when the signs of uterine hyperæmia ceased the joint-affection passed away, there was reason to regard the one as caused by the other. The joint-affection had in itself no necessary property of permanency. The uterine affection had of a necessity a beginning and an end, and the joint-affection was noticed only during its existence. If, from such considerations, it was fair to infer that the dystrophy of joints was, in some way, brought about by an abnormal condition of the uterus, the intermediate conditions linking the two had next to be sought for. That there was some intimate relation between inflammation of the joints and uterine conditions more or less approaching inflammation, had not escaped the acute observation of the late Dr. Todd. In his Croonian lectures for the year 1843, he had written: "It is remarkable how frequently this affection" (the symmetrical nodosities of the hands, called by him "chronic rheumatism of joints") "occurs in women, and how rarely in men; and there are many facts which indicate that, in the former, it may have an uterine origin, either connected with the puerperal state, or from a defective or difficult catamenial action." He was inclined to believe that "the unhealthy secretions of the uterus affords material for the production of rheumatic matter." In these lectures he quotes Sir Henry Holland, Sir Charles Locock, and Dr. Rigby as authorities in favor of the opinion that there is some connection between the sexual functions and the causes and course of gout and rheumatism.

Another good observer, Dr. Fuller, had spoken decidedly as to the fact, that "rheumatic gout attacks women rather than men." "It fixes," he had said, "upon the girl just arriving at puberty, whose menstrual functions are ill performed, and it occurs frequently at the cessation of menstruation or during the debility which follows on a miscarriage, or a difficult or protracted labor, more generally when complicated by flooding." These authors found the explanation of the relation which they so closely acknowledged in the suggestion of a virus, generated in the uterus, absorbed by the blood, and attacking, in virtue of some elective affinity, the joints.

If we consider the many cases in which acute rheumatism occurs immediately after parturition, in the early weeks of lactation, we may acknowledge that the sequence of morbid phenomena lends much support to a hypothesis of this kind. We must acknowledge that the condition of the uterus after parturition provides a large quantity of septic, inflammatory, and quasi-inflammatory matters; that its vascular arrangements are such as to offer a ready access of these matters to the circulation; and that where these matters are undoubtedly septic and where they find access to the circulation, in the septicæmia or pyæmia which follows, the joints are among the organs most frequently invaded by the poison so introduced into the system. But in this, as in other forms, the joints are by no means the only subjects of attack. The viscera are, at least with equal frequency, the seat of this secondary affection. In the acute rheumatism associated with the conditions just mentioned, the serous membranes, and the lungs, and the veins, are frequent sufferers from the inflammation which primarily attacks the joints; but they are more rarely affected without intercurrence of a joint-affection, although, in pyæmia, it is certainly not rare to find the joints spared, while the viscera show fatal lesions. In the nodosity of the joints, which I have presented to you as simultaneous with, and in its variations parallel with, uterine hyperæmia, there is, so far as I have been able to make out, no corresponding visceral inflammation of either an acute or chronic kind. If a blood-condition, having some quality of attenuated septicity, were the agent, the viscera ought in fairness to share in the injury. We may remember that the presence of lactic acid in the blood has been adduced in explanation of the phenomena of acute rheumatism, and, perhaps, more particularly of acute rheumatism breaking out during lactation. This very neat hypothesis has been supported by names of great authority, and rests on the observations that the administrations of lactic acid to men and animals is followed by joint-affection, and that lactic acid has been found in the blood during acute rheumatism. The whole theory resting on these somewhat slender bases cannot, I think, apply in any way to the joint-affections considered in the early part of this address, where the only obvious lines of causation were nervous.

There are not a few considerations which induce me to oppose to this humoral and chemical view the view of nerve-agency. Putting aside those peculiarities of personal constitution which render certain persons prone, under many circumstances involving febrility, to develop joint-affection, particularly acute rheumatism, I would represent that at least a very large majority of the women having nodosity of the joints, or arthritis deformans, present in the first place a marked hyperæmia of the os and cervix uteri. That these organs have the power, through centripetal nervous influence, of producing enormous excitement in the spinal cord is the next point which may be taken. Sometimes the excitement may show itself by pains in the limbs, sometimes by flushings of the skin, sometimes by swellings of the breasts. Sometimes, as it appears to me, the effects of excitement may be reflected along the same paths, which in primary affection of the spinal cord have led to affections of joints. Moreover, the state of the patients under consideration is generally one of debility, often one of anæmia. It is a matter of daily experience that in such conditions the reflex excitability of the spinal cord is increased; it explodes, so to speak, on the application of impulses which, in its proper nutrition, it would transmit. And so both the local and the general state would conduce to the reflection.

Gonorrhœal rheumatism.—There is yet another form of arthritis in which it appears to me possible to call in the agency of the nervous system. I speak of gonorrhœal rheumatism, so called. In this disease, as we know, an arthritis having no differences in its local morbid anatomy from the lesions already discussed comes on during an attack of gonorrhœa, often in company with ophthalmia or sclerotitis. When the gonorrhœa ceases the joint usually gets well. The arthritis is easily induced afresh by new attacks of gonorrhœa. There are, however, some variations in progress and relation. The arthritis sometimes coincides with, sometimes alternates with, the gonorrhœal flow. It sometimes persists, particularly in the knees and ankles, producing chronic changes leading to "white swelling," or a kind of anchylosis. The affection is only seen in males. Ricord gave it the name of "blennorrhagic arthritis," which is to my mind a far better term than gonorrhœal rheumatism. As regards its diagnosis, he asserted that the only real difference between this form of arthritis and all the others is to be found in the cause which gives rise to it. Brodie, Elliotson, Fuller, and others, have cited cases in which a simple, that is to say, not gonorrhœal, urethritis has had associated with it the same three disorders—arthritis, conjunctivitis, sclerotitis. It is hard, of course, to prove a negative, but we have the evidence of the above-named excellent observers, that they at least accepted, in these cases, the absence of gonorrhœal taint as a fact.

I have seen lately a gentleman suffering from a third attack of the kind. He is gouty, lives temperately, but works very hard. On three occasions he has had severe purulent urethritis, which he asserts, to be absolutely un-

connected with any possible source of gonorrhœal kind. This is followed by sharp arthritis, and sometimes by gouty inflammation of the toe, lasting until the discharge, which is very obstinate in resisting treatment, is checked. The patient is a man of the world, and I believe his statement. His own belief is that all the phenomena are gouty.

Blennorrhagic arthritis has naturally been attributed to some specific infection of the system from the urethra, and consequent infection of the joints; but if the concurrence of a similar arthritis with non-specific urethritis be admitted, the theory of a specific poisoning is considerably weakened. If it be acknowledged, again, that so-called gonorrhœal rheumatism is a disease only seen in men, the difficulty of accepting the specific idea is increased.

Women certainly do suffer from gonorrhœa, and I can conceive no reason why, if they have it, they should not be poisoned by it in the same way as men are. The more I think over the matter, the more do I see to suggest a parallel between the nodosity of the joints in women, so often associated with irritation of the uterine surfaces, and the blennorrhagic arthritis associated in men with inflammation of the urethral surface, particularly if the prostatic part of the urethra be affected. That excitements of the prostatic part of the urethra, particularly of the floor, have enormous influence upon the spinal cord, is shown by the phenomena of sexual intercourse. The widespread indescribable sensations which attend emission, and the exhaustion which follows, testify to this. Most of us have, no doubt, been consulted by men, chaste in act, who are tormented by sexual excitement. They tell one stories of long continued local excitement, followed by intense muscular weariness, or by some severe aching pain in the back and legs. In some, I have had complaint of swelling and stiffness in the legs, and of pains in the joints, particularly in the knees. Conditions of this kind indicate an effect upon the spinal cord which is very nearly reacting in trophic influence upon the limbs. I may relate a case in which it seems to me that an actual trophic influence was exerted.

A gentleman, thirty years of age, who had lost his wife about two years before, came to me with painful affection of the knees. Both knee-joints were greatly distended with fluid and were tender, but not much heated. The condition reminded one of the "arthropathie des ataxiques;" but no other sign of tabes dorsalis could be detected then or since. I tried various remedies without success, and he went to many doctors and many baths, without obtaining a cure; though at last with some relief. Then he married again. Not long after he came to tell me that he was quite well. He also told me, upon my asking him as to his bachelor life, that he had been almost constantly harassed by the thorn in the flesh, but that he had been absolutely chaste, and he himself was of opinion that marriage had been the means of cure. I hear of late (some seven years after the second marriage) that his joints are getting bad again, and at the same time that his wife suffers from a uterine affection almost altogether preventing cohabitation. Upon such grounds as the foregoing considerations afford, I suggest it is possible that irritation of nerve-cells in the spinal cord, carried to them through channels of urethral nerves, may set up an excitement in those cells giving rise to irritative processes in the joints supplied by them. M. Charcot's cases already referred to indicate rather a process of inhibition than anything else; of torpor, as he says, of the nerve-cells under centripetal stimulating coming from joints.

Urinary paraplegia.—In relation with the idea that irritation is set up in joints by irritation reflected from viscera, I am tempted to point to the so-called reflex or urinary paraplegia as illustrating, possibly, a torpor set up in the nerve-cells of the cord instead of an irritation dependent on centripetal irritation coming from viscera. The name reflex paraplegia, given by Brown-Séquard, has been of late replaced by a safer term—urinary paraplegia. But, whichever name we use, we recognize that an urethral irritation, most commonly dependent on a stricture, is so joined with paralysis or paresis of the lower limbs as to make it probable that the stricture is a cause of which the paraplegia is an effect. The objection—a just one—to the application of the term "reflex" lies in the fact that the paralysis can sometimes be traced to myelitis in the lower part of the cord, sometimes to neuritis. But in a certain number of cases no lesion of cord or nerves has been detected, and to such cases, where the paraplegia and the urethral irritation were the only coexistences, the term reflex might be applied. I do not speak here of other reflex paraplegias. I merely wish to indicate the possibility of some such nerve-relations existing between the urethral surface of man and the joints, between the uterine surface of woman and the joints, carried on by the mediation of the nerves and cord, and to compare them with such relation as we have been treating of as probably existing between the joints and muscles through the cord.

Enough, you will say, of the joints and their neurotic dystrophies. Too little, I reply, for time forbids me to discuss the neurotic dystrophies of gout.

Neurotic dystrophies of secretion.—I am compelled to go on to another subject, and to direct your attention to some neurotic dystrophies of secretion. Some of the most striking of these are certainly hard to be understood. So far as I am aware, it is not known why the breath of a man, who has undergone great and concentrated mental anxiety, should suddenly become fetid; or why the milk of a woman, whose emotions of fear or anger have been violently excited, should prove poisonous to the infant at her breast.

Glycosuria in relation to nerve-influence.—Suggestions, illustrating the mode in which such dystrophies come about may not unreasonably be afforded from a consideration of what is known with regard to the production of glycosuria. Not long ago I reviewed my notes of cases of glycosuria unattended by diuresis; such cases occurring almost entirely in persons over fifty years of age. Since the time of Bernard's great discovery a long series of experimental physiologists has been engaged in working out the influence of the higher centres, and of the sympathetic in producing glycosuria. Pathological investigation has brought many good observers to the belief that true diabetes mellitus is caused by disease of the central nervous system. It must be admitted that this point is still far from settled. In the non-diabetic glycosuria of comparatively old people, we may see a dystrophy coexistent with disorders of various kinds—disorders, for the most part, more pressing than itself—in such relation that we may be justified in reducing it to the rank of a symptom. If it can be regarded as a symptom, we may have a reasonable probability of arriving at a notion of its causation by an examination of its coincidences or its coexistences. As regards the onset of true diabetes, the frequent antecedence of great emotional disturbance of the central nervous system has been recognized by general consent. Dr. Dickenson has collected a large number of illustrations of this connection in his work on "Diseases of the Kidneys." In the cases which I have analyzed, one-third of the whole number told a story of excessive or prolonged mental work or anxiety preceding the recognition of glycosuria.

In one, after much emotional excitement, insanity was at last fully declared. In one, after a long course of strenuous mental labor, scarcely intermitted during the nights of many years, hemiplegia occurred, and apoplexy ended the chapter. The last two of these cases lead on to another group, in which glycosuria appeared as a symptom of actual disease of the nervous system.

In two cases there was marked tabes dorsalis, and in a third locomotor ataxy was present, with additional signs indicating affection of the whole breadth of the spinal cord. Decided hypochondriasis was noted in two

cases. One of the patients was haunted by the dread of syphilitic disease, but manifested no signs thereof whatever. In a third group marked signs of nervous disorder accompanied the glycosuria, to wit, tinnitus, vertigo, sleeplessness in an extreme degree, constant headache, loss of power, of thought, and memory, numbness in limbs, sciatica, shingles, prurigo, and marked loss of muscular energy. In three cases the patients were the subjects of a very typical form of angina pectoris. I may add that I have since seen another illustration of this coexistence. To sum up, there was scarcely a case in which glycosuria was not associated either with evident disease of the central nervous system, or with symptoms indicating great perturbation of the centres of the nerves. A second stage of observation brings out a new set of relations. In more than a third of the cases true gout was distinctly present; in a much smaller number chronic rheumatoid arthritis. A third of the patients admitted habitual over-indulgence in alcoholic stimulants.

The multiform relations of glycosuria here exhibited would lead to the inference that the ultimate causes are of many kinds. We may recognize the excess of sugar in the blood giving rise to glycosuria as having at least a sixfold origin. Putting aside causes consisting in disproportion between the amount of saccharine matter introduced into the system, and the capacity of the liver for transforming it, or in varying stability of glycogen, or in diminished use of sugar by the system, we come to the discussion of the increased decomposition of glycogen determined by increased afflux of diastatic ferment. To put this in other words, we come to the consideration of dilatation of the hepatic artery and its branches allowing of an increased inflow of ferment-containing blood. By such kind of intermediate influence it is probable that irritations and irritability of the nervous system can be conceived to set up the glycosuria. Irritation of the hepatic nerves in alcoholism and diseases of the liver, irritation of the pneumogastric in the stomach or in the heart, irritations of the pneumogastric arising in other peripheric stimulation can conceivably be reflected in a pathological way, as they are known to be in a physiological way; and in the most typical of the cases which I have analyzed I have had presented to me as causative of glycosuria at the same time signs of deep gastric or hepatic disorder, and signs of general nervous irritability.

Gout and glycosuria.—Gout and glycosuria have been seen in tolerably frequent association in my cases. Dr. Gairdner pointed this out many years ago. Dr. Lauder Brunton has used the term gouty glycosuria. I am tempted, after much thinking, to ask whether the expression "gout of the liver" may not be appropriate; to ask whether we may not entertain the idea that, in many people, there may exist a more or less constant arterial hyperæmia of the liver, comparable to the acute hyperæmia of joints, undoubtedly an essential factor of acute gout.

Acute inflammation of diabetes and nerve-influence.—In true diabetes the occurrence of sudden and very acute visceral inflammations is common. It is generally found that, while such complications last, the urinary sugar dwindles, or even disappears. An explanation of this occurrence has been found by some writers in the hypothesis of an increased combustion of sugar as a part of the pyrexial state. But, seeing that such inflammations involve the diversion of a large quantity of blood to the organ affected, I venture to suggest that in such diversion, rather than in a purely hypothetical combustion, may be found the true explanation. Physiological experiment has shown that, when sections of the sympathetic leading to vaso-motor dilatation of the hepatic vessels alone has been made, glycosuria has been produced; that, when the section has been made at a point producing, in addition to dilatation of the arteries of the liver, dilatation of the vessels of the intestines, glycosuria has not followed. The inference drawn is to the effect that so much arterial relaxation was produced in the supply of organs neighboring to the liver as to stand in the way of an effective increase in its arterial circulation. I had an opportunity quite recently of testing the probability of this hypothesis. The temperature of a diabetic patient rose suddenly to 104° Fahr. The most careful examination brought out no signs of visceral inflammation during two days, and in the same period the amount of sugar in the urine stood at the figure registered for several weeks before. On the third day, the temperature remaining at the same height, the signs of pneumonia became apparent, and at the same time the urinary sugar diminished very considerably. In my gouty cases a similar train of phenomena has been several times noted—the sugar diminishing in a very marked degree at the time of the development of acute joint-inflammation, and returning immediately on its subsidence.

In trying to understand the sudden acquirement of a poisonous quality by the milk of an agitated woman, one had found a difficulty of this kind—could mere quantitative variations in the afflux of blood affect the quality of the secretion? Can it be possible that, in the production of the lacteal secretion, may be concerned not merely increased afflux of the materials of the secretion, but also varying afflux of ferments determining its quality, and capable, by reason of either great deficiency or great excess, of seriously perverting its quality? Here is an admitted neurotic dystrophy, the mechanism of which is well worth careful investigation; and from the consideration of glycosuria we may be enabled to glean at least suggestions as to what the mechanism may be.

The nervous relations of myxœdema.—Let me, leaving many points which are tempting, go on to say a few words about another class of neurotic dystrophies, namely, about those occurring in myxœdema, occurring therein to such an extent as to constitute the predominant symptomatology of that disease. We may recognize in myxœdema three principal lines of nervous abnormity.

First, intellectual, consisting in slowness of thought, in slowness of volition, in loss of memory, in irritability of temper, in unwarranted suspicions, in delusions, in actual insanity, or in torpor growing to coma.

Second, in sensation. General sensation undergoes a change, to which the term bradyæsthesia is applicable; the recognition of impressions made on the surface is distinctly retarded; the sensibility to sensations of heat or cold is blunted; and there are often noted abnormal subjective sensations, particularly affecting the sense of taste and smell.

Third, the motor powers are disturbed in a singular way; all motion is slow; co-ordination is imperfectly adjusted; certain groups of muscles become unduly relaxed, and are stimulated to action only by strong exercise of volition. Reflex actions are produced with considerable delay. In some cases evidences of more localized nervous impairment occur, in particular the signs of bulbar paralysis. It may be argued, on the one hand, that this remarkable assemblage of nervous disorders points to the nervous system as the seat of the original cause of the disease; on the other, that the obvious changes in the state of the connective tissues throughout the body may affect the nervous centres and put their morbid reactions into the category of secondary conditions. It is a question, that is to say, whether myxœdema be a neurotic dystrophy, or whether the disorders of the nervous system are produced by an alteration of connective tissues, having an origin, like that for instance of lardaceous disease, independent of nervous influence—chemical, degenerative, inflammatory, or other. The remarkable atrophy of the thyroid body observed in this disease, and the relation which is by many regarded as existing between that body and the sympathetic system, have brought some thinkers to the belief that the disease arises primarily neither in affections of the cerebro-spinal system, nor in altered nutrition of the connective tissues. Those who are induced to take this view

have found the explanation in primary alteration of the sympathetic system; in alteration of the sympathetic system somehow determined by the atrophy of the thyroid, or in alteration of the sympathetic system determined by chronic apyretic inflammations within the chest, particularly in the pleura. What can be said is, that in this disease there can be recognized an enormous dystrophy of connective tissues; that the dystrophy has certain aspects of degeneration; that, again, in the increase of nuclei, it has some aspect of over-activity; and that, so far, it may suggest the occurrence of a low form of inflammatory process inducing degeneration of the tissues involved; or that, on the other hand, a degeneration has induced a very elementary inflammatory process in the tissues.

The atrophy of the thyroid may conceivably be brought about by the changes of the connective tissue which we can see in the other parts of the body, leading, by the aggressive hypertrophy of that tissue, to pressure on, and atrophic changes in, immeshed glandular tissues. But here we must hold our hand, for there is another side to the question. Kocher and others in Switzerland have of late years been cutting out enlarged thyroid glands, and have recorded the sequence upon this operation of slow development of a condition which, as produced and described by them, corresponds exactly with myxœdema as observed in England. The interest of the observation is intensified by the circumstance that these operators in making this record were not aware of the observations on myxœdema, made in this country.

The true function of the thyroid body being undetermined, one may hope that the concurrent observations may converge in such a way as to throw light on a very obscure bit of physiology; but it is hard to resist the conclusion that, through some nervous channels, the thyroid body influences the nutrition of the connective tissues generally, and may, perhaps, also influence the nutrition of the cerebro-spinal centres.

To put the matter in another way, the great tendency of existing observations is to class myxœdema among neurotic dystrophies.

I should have liked, if I could have brought them within the compass of this address, to have said something about the neurotic dystrophies of the skin, but must, however, reluctantly leave them untouched.

Many here will think that I should have said something about the dystrophies incited by surgical injuries of nerves. These last, indeed, offer possibilities of more exact treatment than any of the dystrophies which have engaged our attention. The observations of Weir Mitchell, Brown-Séquard, Hutchinson, and others have been, in some unconscious fashion, directing my thoughts to the choice of the subject of to-day's address. Let me acknowledge this fully; and let me ask you to understand that I have to-day merely been putting before you the result of observation and thought set going by the reading of the works of predecessors and contemporaries. Each succeeding generation in science gathers the lines of older and recent vision into some focus more or less of its own choosing. The wisdom of the choice is to be judged by the generations still succeeding. What shall be the outcome here?

A Rare Human Tapeworm.—Dr. Leidy describes in *The American Journal of the Medical Sciences* for July, 1884, the tænia flavopunctata, a rare human tapeworm, which has now been observed for a second time, both cases occurring in this country and infesting children. It is not improbable that the species is more common than the observations would warrant us in believing, for from the smallness of the worm and the generally prevailing ignorance of the distinctions in the more common species, it might readily be passed for immature portions of these.

CEREBRAL LOCALIZATION—THE CENTRES FOR VISION.

By PHILIP ZENNER, A.M., M.D.,

CINCINNATI, O.

(Continued from page 149.) †

Physiological data.—Fritsch and Hitzig, in 1870, first made known to the world that irritation or removal of certain parts of the cerebral cortex was followed by definite motor phenomena, or the disturbance of the cerebral functions. Their experiments made it highly probable that different parts of the cortex have different and distinct functions. Their results were soon corroborated and extended by Ferrier, and since then there have been numerous contributions of the same kind.

Experiments of Munk.—It is not my object to enter into any historical disquisition, but rather to give those experimental researches which bear directly on our subject. I shall, therefore, begin immediately with the experiments of Munk, which, from the precision and completeness of their results, have excited universal admiration. We will consider them only so far as they are concerned with the sense of vision.

Munk's experiments were made upon dogs and monkeys, chiefly the former. The conclusions drawn from them were: 1, in the dog the visual centre is in the occipital region, the visual area of each hemisphere being in relation with both eyes, though to a much greater extent with the eye on the opposite side than with the one on the same side; 2, in the monkey the visual centre is in the occipital lobe, one hemisphere being in relation with one-half of each retina.

Munk reported his results at various meetings of the Physiological Society of Berlin, in the years 1877–80. Each successive report contains the additional knowledge gained from his latest experiments, and becomes especially interesting on account of the manner in which former statements are amplified or corrected. There is something in the gradual development of his views which apparently adds to their weight, and the more easily convinces us of their correctness. In order to give a better idea of these admirable experiments, I will give a brief summary of his reports:[1]

He began by removing small circular segments, fifteen millimetres in diameter and about two millimetres in depth from the convexity of the brain (of dogs) in various localities. Only when the part removed was in a limited area of the occipital region was there any appreciable impairment of vision. When the lesion was produced in this region it was followed by peculiar disturbances of sight. The affection of vision was observed only in the eye opposite to the injured hemisphere. When the sound eye was covered, so that he could only use the affected one; or, in case a symmetrical lesion had been produced in both hemispheres when both eyes were uncovered, it was observed that the animal no longer recognized objects formerly familiar to him. Thus, he remained unconcerned and quiet when a whip was held before him, at the sight of which he had previously been accustomed to wince or run away. A bright light brought suddenly before the eyes caused no movement, and he remained impassive in the presence of food until, through some other sense—taste, smell—he became cognizant of its presence. Yet the dog was not blind, for he avoided any obstacle in his way. At the end of from four to six weeks this visual defect gradually disappeared, and objects were recognized as before.

Munk supposed that the removal of this area in the cortex did not produce blindness, but that it robbed the brain of that part wherein were stored the visual images gained from past experience, leaving the animals, therefore, like new-born, who see, but do not know the meaning of what they see. The fact that after the lapse of a few weeks they again recognized objects he attributed

[1] Taken from Functionen des Grossheinrinde, Gesammelte Mittheilungen.

to knowledge gained from new experience. This condition, in which animals, while retaining the sense of vision, had lost the knowledge that vision usually conveys, he termed "soul-blindness" (*seelen blindheit*).

Later and more careful observations revealed that there was in these instances not only this mental blindness, but, at least for parts of the retinæ, complete blindness. It was observed after the soul-blindness had disappeared that when pieces of meat were scattered on the floor, the dog would find some pieces and overlook others. In brief, in those animals in which the specified part of the cortex had been removed there was absolute blindness of the central (the most important) part of the retina of the opposite eye, while the peripheral portions of the same retina remained intact. The size of the blind spot in the retina was in proportion to the extent of visual area destroyed.

Munk now removed what he supposed to be the entire visual area of one hemisphere, the cortex of the whole occipital region. At first the animal made the same impressions as those above described, in the one eye vision being apparently normal, in the other the so-called soul-blindness. But that this conclusion was not quite correct was shown by closer observations. When the sound eye was covered objects held in front of the other were apparently not seen. But if now the object was placed just before the covered eye, so that its image fell on the temporal side of the retina of the affected eye it then seemed to be observed. Vision was retained in its temporal segment while the rest of the retina was paralyzed. But there was for this still sensitive portion the condition described as soul-blindness—objects were seen but not recognized. But the animal could very readily be taught to again recognize the forgotten objects. Thus, when food was placed where its image fell on the sensitive portion of the retina it was at first left untouched. But when the animal learned what it was from his other senses, he soon recognized it by sight alone. A light held in the same position left the animal unmoved, but after he had been singed with it, its mere appearance produced manifestations of fear.

While after entire removal of the visual area of one hemisphere there was thus partial blindness in the opposite eye (the larger part of the retina being paralyzed, a smaller part on temporal side remaining sensitive to light), a contrary condition was found in the eye of the same side. Here central vision was perfect; but on careful examination it was observed that there was a small segment of the retina on the nasal side, corresponding in size to the sensitive portion of the other retina, where light was no longer perceived.

In seven dogs Munk succeeded in removing the entire visual area of both sides. They all lived several months (one of them six months) after the operation. In all of them, while the other senses and power of movement remained unimpaired, the sense of vision was lost in both eyes completely and permanently.

„There could scarcely be a more complete demonstration of the cortical centres for vision than these admirable experiments of Munk. It only remains to point out more precisely the relations of the retina to the visual area. This Munk succeeded in doing with a wonderful degree of precision. His results are as follows: The outer part of the visual area (about one-third of entire visual area) is in relation with the outer or temporal part of retina (about one-fourth entire retina) of the same side. The larger inner and median part of the visual area is in relation with the larger inner and central part of the retina of the opposite side. The outer segment of the visual area is in relation with the corresponding outer segment of the retina in such a way that the inner part of the former is in relation to the inner part of the latter, the outer part in relation to the outer part of the latter. The same relationship exists between the other corresponding segments, that is, the outer part of the inner and median segment of the visual area is in relation with the outer part of the corresponding inner and central segment of the retina, and, again, the inner part of the one in relation to the inner part of the other. To complete this topographical relationship, it need only be added that the anterior parts of the visual area are in relation with the superior, the posterior in relation with the inferior portions of the retina.

Lest the above may not be altogether clear, I will repeat the description of relationship of cortex and retina in Munk's own words: "Each retina in its outer lateral part is devoted to the most external lateral portion of the visual area of the same side. The much larger remaining part of each retina belongs to the much larger remaining portion of the opposite visual area, and in such a way that we may imagine the retina projected upon the visual area with the lateral border of this larger segment of the retina corresponding to the lateral border of the larger segment of the visual area, its most internal border to the median border of the latter, and, finally, the superior border of the retina to the anterior, the inferior to the posterior border of the visual area."

The results of Munk's experiments on monkeys have already been mentioned. They were made on a smaller number of animals, and lead to the general conclusion that the visual area is seated in the occipital convolutions, each occipital lobe being in relation with a corresponding half of each retina. We thus see that in the monkey the occipital lobe is in relation with a larger segment of the retina on the same side than in the dog, and in this respect is similar to what we will have occasion to observe in man.

These, then, very briefly given, are the results of Munk's experiments on dogs and monkeys. Ganser[1] observed, after removal of the occipital region in cats, blindness on the corresponding side of both retinæ. The results obtained by other experimenters, especially Ferrier, will be mentioned at a later period; but we must now proceed to examine the experiments of an eminent physiologist, Goltz, who has apparently obtained results contradictory to those just mentioned, and who has succeeded in exciting much doubt as to the correctness of the present theories of localization.

Experiments of Goltz.—Goltz has made various reports of his experiments, but of his original contributions only one, that published in the first volume of the "Transactions" of the last International Medical Congress, is at my disposal. The statements here made are taken chiefly from that article. A few of his experiments mentioned by Wernicke,[2] not included in the above report, will be added. Goltz' general conclusions are: Destruction of a large part of the cerebral cortex weakens all its higher functions, it diminishes the intelligence and thereby the acuity of all the special senses. But the destruction of no part is followed by the complete or permanent loss of any cerebral function, with slight modifications all being always alike affected, the degree depending only on the extent of the injury. In other words, we cannot say of any part that it is the centre for vision, hearing, the innervation of certain groups of muscles, or the like.

The experiments were made on dogs. In the beginning he was accustomed to remove portions of the brain substance by means of a stream of water, large parts being washed out at one time. He observed, after thus removing a large part of one hemisphere, hemiplegia on the opposite side, and blindness in the opposite eye. But these symptoms were only transitory. Soon the animal appeared to use one side as well as the other; and the eye again saw, though certain disturbances remained. Although he avoided obstacles in his way, he no longer recognized persons, was not frightened when threatened with a whip, etc.; in short, the condition above described as soul-blindness. Goltz at the same time observed similar defects of the other special senses. The dog ap-

[1] Archiv f. Psychiatrie, Bd. xiii., 1882.
[2] Gehirnkrankheiten. Introduction to vol. ii.

parently retained the sense of hearing, but was not frightened at the cracking of a whip as before, etc. Inasmuch as the symptoms were much alike, whatever part of the brain was washed out, Goltz believed that the present theories of localization must be incorrect. But for the purpose of examining the question more carefully, he instituted another series of experiments, wherein, instead of removing brain substance by means of a stream of water, he employed a boring-machine, wherewith he was enabled to remove much more circumscribed parts.

His general conclusions are the same here as from the former series of experiments. From small lesions he observed no permanent injury of intelligence or special senses, from large lesions (and such were produced in most instances) the general results already mentioned. In confirmation of his views he exhibited before the International Congress in London a dog in whom he had removed, at five different periods, from November 15, 1880, to May 25, 1881, large portions from the parietal and occipital regions of both hemispheres. This dog could run along in a lively manner, revealing no evidence of paralysis of any muscles further than a certain awkwardness in some of his movements. He was not blind, as evinced by his avoiding obstacles. But he manifested no fear when threatened with the fist or whip, or when a flame was brought in front of his eyes. He could hear, for he turned his head when called and tried to reach the caller. But he heard unmoved the cracking of a whip, which formerly produced the liveliest manifestations of fear. He could smell, but did not object to tobacco smoke or chloroform vapor. He could taste, but would eat the flesh of a dog, formerly very objectionable to him. Finally, his cutaneous sensibility was retained, though blunted. The dog's intellect was greatly impaired, and Goltz attributed the various sensory disturbances just detailed to the great lack of intelligence.

It is on experiments and observations of this kind that Goltz bases his views. Yet, when properly considered, they by no means have the full significance he attaches to them.[1] My present remarks refer to his conclusions only on the subject of vision. As to the motor phenomena in these instances, they must be explained in quite a different manner.[2]

According to the experiments of Munk, the extirpation of parts of the visual area is attended by permanent defects of vision, which defects are only detected after very careful observations. That Goltz made special examinations for the purpose of discovering whether such defects were present, whether there were larger or smaller blind spots in the retinæ, does not appear from his report. If but a small part of the visual area remained, that would probably be accompanied by sufficient vision to avoid obstacles, etc., which appeared to be the only evidence of sight in Goltz' animals, when large parts of the brain were removed. Only in case he had removed the entire visual area of Munk without producing complete blindness could it be said that Munk's statements had been disproven. It is true, Goltz claims to have done this. But we may be allowed to doubt this statement (at least so far as Munk's description of the visual area is concerned), for he speaks of the entire removal of the visual area of the dog presented at the International Congress, though a large part of it still remains.

But what Goltz dwells upon specially, as seeming to disprove former theories of localization, is that in his experiments the removal of the so-called visual centre caused equal defects in the other special senses, hearing, smell, etc. As an objection to the correctness of such reasoning it must be mentioned that in such instances large parts of the brain had been removed. Thus not only were parts of the surface removed, which presumably belonged to other centres, but the deeper portions of the brain were extensively injured, and thus fibres severed passing to various portions of the cortex. That such lesions should be followed by the impairment of more than one function is not surprising, but what ought to have been expected.

But apart from these considerations Goltz' experiments in some instances are opposed to his own views. The following illustrations are taken from Wernicke's summary of Goltz' experiments.[1] A dog, in whom the cortex of one occipital region was removed, five weeks after the operation saw only imperfectly with the opposite eye, while no other defect was noticeable. In another instance, where portions were removed from both hemispheres, vision was very imperfect while hearing was apparently normal.

The last instance I shall mention is the dog presented at the International Congress. This case is the more worthy of careful study because not only was it publicly demonstrated, but the post-mortem examination was made by a commission of impartial judges, giving it the value not alone of individual but also of general observation.

I believe in this case there is evidence of paralysis of parts of the retinæ. The dog did not fix objects with his eyes, as is usual in looking at things; when called and attempting to find the one calling him, he moved aimlessly about; and in moving about he often struck against objects on the left side, which seemed to indicate blindness in the left part of the field of vision, and may be brought in direct relationship with the fact made evident both by the written description of the post-mortem, and by the accompanying plates, that the visual area in the right hemisphere was removed to a much greater extent than that in the left.

We have dwelt sufficiently on the experiments of Goltz. If, notwithstanding the eminence of the experimenter, we cannot accept his views, we are influenced not alone by the results gained by other experimenters, but also by the critical study of his own results.

Topography of cerebral convolutions.—Before leaving this part of our subject I must enter briefly into a few anatomical details. The object of our present investigations is to arrive at a knowledge of the functions of parts of the convexity of the brain. We have thus far considered mainly the results of experiments on animals, and will have next to study pathological changes in man. But in order that there may be a comparison between such results we must know that the parts are anatomically homologous, in order to attribute to them like functions, but in appearance this is not the case. It will have been observed that in reference to rabbits, cats, and dogs, I have spoken of the occipital region, and in man and monkey of the occipital lobes and convolutions. For the latter can be distinctly mapped out in man and the monkey, but not in the other animals mentioned.

In most of the higher mammalia there are to be seen in the convexity of each hemisphere four longitudinal convolutions which pass from the anterior to the posterior part of the brain, arching over the Sylvian fissure. These are usually termed the four original convolutions, the one bordering the longitudinal fissure the first, that bordering the Sylvian fissure the fourth convolution. In lower mammalia, as the rabbit, there are only indistinct sulci on the surface of the hemispheres, and no convolutions distinctly mapped out. In the monkey and man, on the other hand, this four convolution type appears to have been wiped out through the appearance of new features, especially the fissure of Rolando, and the occipital fissures, thereby multiplying the number of convolutions.

---

[1] This statement and the following ones are based upon the knowledge of Goltz' experiments and conclusions as found in the report to the International Congress. As in this report he reviews the whole subject, we are perhaps justified in judging it as it stands. If there be anything in his other contributions which apparently nullifies any statement of mine, I regret that such are not within my reach.

[2] Ferrier's explanation is probably a correct one, that the lower the animal the greater the independence of the subcortical centres; so that in dogs locomotion is still possible after removal of the cortical centres of motion, while in the monkey and man, where the hemispheres have a far higher influence, such mutilation will cause permanent paralysis.

[1] Loc. cit.

Nevertheless a careful study of their development, and of brains of different races, where the type gradually changes to these more extreme forms, enables us to trace a topographical relationship between the more highly developed convolutions of the monkey and man, and the four convolution type of other mammalia. It thus appears that the occipital convolutions are the posterior extremities of the second and third original convolutions; and the angular gyrus (a part we will have occasion to refer to again) is a part of the original third convolution.[1]

I may mention here that our future investigations will lead to the conclusion that the cortical visual area in man is mainly in the occipital lobes, the part corresponding to that pointed out by Munk as the visual area in the dog, and probably also to that in the rabbit as mapped out by Monakow.

AGE OF GREATEST RISK FROM CONSUMPTION.

By HENRY B. BAKER, M.D.,

LANSING, MICHIGAN.

On page 36 of THE RECORD for July 12, 1884, I am glad to find an article, illustrated by a diagram, showing the death-rate from consumption at several periods of age from twenty to over seventy years. Some years since I prepared and published in a volume distributed in Michigan ("The Vital Statistics of Michigan, 1870"), issued in 1872, a similar diagram relating to the deaths returned as having occurred from consumption in the State of Michigan in the year 1870, 1,451 deaths in all, in which the increased proportion of deaths to inhabitants over the age of fifty-five years was especially noticeable. The subject is one which may justly claim the attention of the physician as well as the student of vital statistics. The death-rate of females was much greater than that of the males at ages from ten to fifty-five years, except that at the period from forty to forty-five years of age the death-rate of women from consumption dropped very noticeably; but at ages fifty-five to seventy-five years the death-rate of males was greater than that of females, from this disease. The number of deaths of those above the age of seventy-five years is too small to give a steady curve, but the table, and especially the diagram, shows well the death-rate of each sex from birth to the age of seventy-five years. The death-rate from consumption was then shown to be least at the ages from five to fifteen years. The remarks then made in connection with the subject, show the reason for the fallacy in the popular view that the death-rate is greatest at ages twenty to twenty-five or twenty to forty; the *number* of deaths being greatest at ages twenty to twenty-five, the fact of the much greater proportion of inhabitants at those ages than at the older ages is not generally held in mind.

THE RELATION BETWEEN NERVOUS AFFECTIONS AND DISEASES OF THE NOSE.—Dr. Chiari relates three cases of nervous affections caused by swelling of the mucous membrane covering the inferior turbinated bones. In two of these cases there was supraorbital neuralgia, which was entirely relieved after the removal of a number of nasal polypi. The third patient suffered from bronchial asthma. Although there seemed to be sufficient cause for the trouble in an aneurism of the aorta, nevertheless the author determined to reduce a slight swelling of the mucous membrane covering the anterior portion of the turbinated bones. This was done by means of the galvano-cautery, and the result was a perfect cure of the asthma. Dr. Chiari holds that one ought to search the nostrils for a possible cause of asthma in every instance, even though the condition of the heart or lungs would seem to offer a sufficient explanation of the dyspnœa.—*Deutsche Medicinal-Zeitung*, June 9, 1884.

Progress of Medical Science.

PERSISTENT OMPHALO-MESENTERIC REMAINS.—The pouch-like formation of intestine occasionally seen projecting from the lower portion of the ileum, is universally known as Meckel's diverticulum. Not that this distinguished anatomist was its discoverer, but to him we owe not only the almost universal acceptance of his theory of the origin of the pouch in question, but are also indebted to him for calling conspicuous attention to its importance in the causation of serious disease. In an article in the July number of *The American Journal of the Medical Sciences*, Dr. Fitz, of Boston, considers this whole subject and points out that the view—that most, if not all well-authenticated instances of duplication of the intestinal tract, at any part of its course, are the probable result of the persistence and growth of the remains of the vitelline duct—is rendered highly probable from what is known concerning the development of the intestine. Attention is also called to cystic dilatation of the diverticulum. These retention cysts, as they are called, may have their cavity continuous or discontinuous with the intestine. Moreover, such cysts of possible intestinal origin are not limited to the abdominal cavity, having been observed in the vicinity of the œsophagus, in the abdominal walls, in the vicinity of the umbilicus.

Dr. Fitz points out that the vitelline duct is composed not only of layers of tissue equivalent to those forming the coats of the intestine, but it is also accompanied by blood-vessels. The relation of these omphalo-mesenteric vessels or their remains to intestinal strangulation is fully discussed, and the importance of bearing in mind the congenital nature of certain of the causes of acute intestinal obstruction is earnestly insisted upon. Dr. Fitz finds that—1. Bands and cords as a cause of acute intestinal obstruction are second in importance to intussusception alone. 2. Their seat, structure, and relation are such as frequently admit their origin from obliterated or patent omphalo-mesenteric vessels, either alone or in connection with Meckel's diverticulum, and oppose their origin from peritonitis. 3. Recorded cases of intestinal strangulation from Meckel's diverticulum, in most instances, at least, belong in the above series. 4. In the region where these congenital causes are most frequently met with an occasional cause of intestinal strangulation, viz., the vermiform appendage, is also found. 5. It would seem, therefore, that in the operation of abdominal section for the relief of acute intestinal obstruction not due to intussusception, and in the absence of local symptoms calling for the preferable exploration of other parts of the abdominal cavity, the lower right quadrant should be selected as the seat of the incision.

The vicinity of the navel and the lower three feet of the ilium should then receive the earliest attention. If a band is discovered, it is most likely to be a persistent vitelline duct—*i.e.*, Meckel's diverticulum, or an omphalo-mesenteric vessel either patent or obliterated, or both these structures in continuity. The section of the band may thus necessitate opening the intestinal canal or a blood-vessel of large size. Each of these alternatives is to be guarded against, and the removal of the entire band is to be sought for, lest subsequent adherence prove a fresh source of strangulation.

ON OPENING AND DRAINAGE OF ABSCESS CAVITIES IN THE BRAIN.—Drs. Fenger and Lee, in a paper on this subject in the July number of *The American Journal of the Medical Sciences*, consider the treatment of traumatic cerebral abscess, and report a case which was successfully treated by opening and drainage.

Bergman, in discussing the treatment of cerebral abscess, unhesitatingly sets it down as an axiom that wherever there is an accumulation of pus, trephining is most clearly and indubitably indicated, for the opening of an abscess in the brain is as necessary as in any

other part of the body, and we would add even more so. A correct diagnosis of abscess having been made, the further difficulty presents itself of locating it with sufficient accuracy, so as to be able to find it. A number of cases are on record, in which a correct diagnosis had been made, the trephine also put on more or less at the right place, but the knife or trocar being passed into the brain, nevertheless missed the abscess. Drs. Fenger and Lee show by their case that this difficulty can be obviated by multiple exploratory aspirations, performed at interstices sufficiently small to prevent any abscess from escaping detection, even if the trephine opening should not have been made at the point of the skull nearest the abscess.

There are on record a large number of cases of cerebral abscess in which trephining was performed, pus evacuated, and temporary relief obtained; but later relapse followed, and a fatal termination ensued. It is possible, judging from the success the practice has met with in the treatment of abscesses in other situations, that drainage of the cerebral abscess-cavity, with or without washing out, would have saved some of these cases, by preventing the reaccumulation of pus and the continuous infection of the surrounding brain tissue, the acute œdema of which is well known to be, as a rule, the final cause of death. As far as Drs. Fenger and Lee are aware, draining and washing out of cerebral abscess-cavities has heretofore not been tried; that it can be effected and without any detriment to the patient, is shown by their case, the treatment of which they hold strictly conforms to the rational methods of modern surgery in treating abscesses in general; and because of this, and not because their patient recovered, they regard the case as answering affirmatively the question: Is it probable that abscesses in the brain can be treated advantageously on the same principles as abscesses in other parts of the body?

Aspiration of the Bladder.—Dr. Hamaide relates some instances of impervious stricture of the urethra in which he aspirated the bladder from thirteen to eighteen times without observing any unpleasant symptoms. He cites these cases as an additional evidence of the safety of this procedure, and he maintains that aspiration is much less likely to do harm than is catheterization in unskilful hands.—*Journal de Médecine de Paris*, No. 21, 1884.

Traumatic Cephalhydrocele.—The occurrence of subfascial accumulation of cerebro-spinal fluid, in connection with and consequent upon simple fracture of the vault, is of great rarity. Two cases of this kind are recorded by Dr. P. S. Conner, of Cincinnati, in the July number of *The American Journal of the Medical Sciences*. So far as he has been able to ascertain, there have been reported but nineteen similar cases, and three others where there had been originally a communicating wound of the scalp which had closed. As far as has yet been observed, excluding those cases which were primarily compound, this traumatic cephalhydrocele is met with only in young subjects. Explanation of this fact is probably to be found, at least in part, in the great elasticity of the skull in infancy and early childhood, permitting of marked depression and fissuring of the vault without that associated wound of the scalp which would be likely to occur were ossification complete; and in part, also, in the much closer connection of the meninges and skull in children than in youth and adults. The decided gravity of these cases is apparent from the statistics. Of the eighteen cases of simple fracture in which the result is known, nine (fifty per cent.) died—eight of meningo-encephalitis and one of erysipelas and meningitis; and of the three in which the fracture was originally compound, one died (thirty-three and one-third per cent.) of cerebral abscess. Even the supposed recoveries may be regarded with some suspicion, because of too early report. Dr. Conner draws the following general conclusions: 1. Simple fracture of the vault of the skull may give rise to a collection under the scalp of the cerebro-spinal fluid; coming, it may be, only from an opened ventricular cavity. 2. Such traumatic cephalhydrocele may be developed quickly, or only after the lapse of a number of days, or even weeks. 3. The condition is one that has thus far been noticed only in young subjects. 4. The accident is quite likely to prove fatal from lepto-meningitis or meningo-encephalitis. 5. Operative interference should be restricted to the removal by aspiration of a limited amount of fluid; and such aspiration should be made only when severe pressure symptoms have manifested themselves. 6. A similar fluid accumulation may occur after closure of the external wound of a compound vault-fracture or of a trephining.

Purification of Drinking-Water.—The following method, proposed by Professor Almen, of Upsala, is recommended by Husemann: To a quart of water are added a drachm of a 5 per cent. solution of chloride of iron, and from 1½ to 2 ounces of lime-water. The ensuing reddish-brown precipitate removes all the floating particles and from 40 to 80 per cent. of the soluble organic matters. When this precipitate has settled to the bottom, the water is filtered through sand or fine linen. —*Deutsche Medicinal-Zeitung*, June 5, 1884.

The Etiology of Convulsions in Children.—There is a special predisposition in children to convulsions, and this is due, according to Professor Kjellberg, not to any increased irritability in the motor or sensory tracts or in the reflex centres, but to the fact that the brain is unable to exercise any controlling influence upon the reflex centres. Convulsions which occur at the commencement or during the course of any acute disease through direct central irritation are symptomatic. Those which are excited reflexly by irritation of the sensory nerve-endings are sympathetic. Symptomatic convulsions are due in part to disturbances in the circulation and in part to changes in the blood. Among the disturbances in the circulation, the most common is a rapidly produced cerebral anæmia. This may be caused by hemorrhage, a rapid waste of the animal fluids, or arterial spasm. In other cases it is due to cerebral compression or anatomical changes in the brain, such as extravasation of blood, tumors, softening, etc. Hyperæmia may also cause convulsions indirectly. When an excess of blood is carried to the brain the cerebro-spinal fluid in the perivascular spaces cannot yield, but makes pressure on the smaller capillaries, whereby they are emptied of their blood, and the real condition is then anæmia of the brain. The action of venous stasis is very similar in depriving the brain of its necessary supply of arterial blood. There are often changes in the blood at the same time with these circulatory disturbances. An elevated temperature is one of the most potent of these causes, as by it the irritability of the nerve-elements is increased. The quality of the blood may be impaired also by the introduction of poisons, either those introduced from without or those formed in the tissues of the body itself. In this category belongs also the change in the milk of nursing women induced by violent emotion. Sympathetic convulsions may be excited by almost any irritation of the sensory nerve-endings, in consequence either of increased irritability of the nerves or of diminished power of the reflex controlling centres. In regard to the presence of worms in the intestinal canal, the author admits that this may be a cause of convulsions, but insists upon the necessity of a search for other causes, since worms may be present and yet have nothing to do with the convulsions. He believes also that dentition may be of etiological importance, and does not admit as valid the objections of those who say that this is a physiological process, and therefore incapable of producing morbid symptoms. Although he does not doubt the fact of an hereditary predisposition to convulsions in certain families, he admits his inability to explain it.—*Schmidt's Jahrbücher*, May 20, 1884.

Cortical Lesions of the Brain.—Dr. M. Allen Starr, of New York, in the July number of *The American Journal of the Medical Sciences*, has collected the American cases of lesions of the central region of the brain, and carefully studied their localized symptoms. He finds that disturbance of general sensation—including the sense of touch, pressure, pain, and temperature, together with the sense of the location of a limb—may occur either in the form of subjective perceptions of such sensations without objective cause, or in the form of impairment of these sensations. In either case it indicates a disease in the central convolutions, and possibly in the adjacent portion of the parietal lobules. The power of voluntary motion of the muscles of the opposite side of the body is located in the two central convolutions which border the fissure of Rolando. Motions of the face and tongue originate in the lower third of this region; motions of the arm, in the middle third; motions of the leg, in the upper third. Spasms in, or paralysis of, a single group of muscles may indicate disease of its motor area. Extensive spasms or paralysis may indicate a large area of disease in this region, but if more marked in a single group of muscles than in others it may indicate a small focus of disease in the motor area of that group affecting other motor areas indirectly and coincidently. Paralysis following spasm in one group of muscles is a characteristic symptom of disease in the central region. Disturbance of the power of speech indicates disease in the convolutions about the fissure of Sylvius on the left side in right-handed persons, and on the right side in left-handed persons. If the patient can understand a question and can recall the words needed for a reply, but is unable to initiate the necessary motions involved in speaking, the disease is probably in the third frontal convolution and in the adjacent portion of the anterior central convolution. If the patient cannot recognize spoken language, but can repeat words after another, or can use exclamations on being irritated, the disease is probably in the first temporal convolution. If the patient can understand and can talk, but replaces a word desired by one that is unexpected, the disease is probably situated deep within the Sylvian fissure, or in the white substance of the brain, and involves the association fibres which join the convolutions just named.

Bright's Disease of Malarial Origin.—Dr. I. E. Atkinson, believing that this subject has not attracted the attention it deserves, has been led to study with reference to it all cases of malarial fever coming under his observation during the late summer and early fall of the past two years at Bayview Asylum, and the result he gives in a paper which appears in the July number of *The American Journal of the Medical Sciences*. The conclusions which he reaches are as follows: 1. Transitory albuminuria is not uncommon in the course of malarial fevers, and is due to the intense visceral congestions characteristic of these affections. It only may endure throughout the height of the congestion, recurring with each return of this, or it may persist in the intervals, in which event a higher grade of congestion is attained, more nearly approaching a condition of acute inflammation. 2. In a proportion of cases, varying with locality and type of prevailing epidemic or individual conditions, inflammation of the kidney occurs, accompanied by dropsy and the usual symptoms of nephritis. 3. The usual form of malarial nephritis is the tubal and diffuse variety. In this the inflammation seems to be most intense in the vicinity of the glomeruli. 4. Contracted kidney may occur as an advanced stage of malarial nephritis either from long-continued or frequently repeated attacks of malarial fever, or from fibrotic changes such as may ultimately occur in ordinary tubal or diffuse nephritis. It is altogether improbable that this form of malarial renal disease ever occurs primarily as purely interstitial nephritis. 5. These changes may be induced by any form of malarial fever, though they more commonly follow chronic intermittent fever. 6. The tendency of malarial inflammation of the kidney is toward recovery. But from the persistence of the impaludism or the intensity of the inflammation, structural changes may be produced that are characteristic of chronic Bright's disease, when the gravity of the affection will be as that from chronic Bright's disease from whatever cause. 7. Treatment should be directed primarily against the malarial intoxication, more especially in recent cases. A correction of this will often be followed by a complete, though often gradual, subsidence of the nephritis. Even in more chronic cases, the malarial factor in the process should definitely be destroyed if possible, after which the disease should be treated as ordinary Bright's disease.

Nerve-Stretching in the Treatment of Epileptiform Neuralgia.—Epileptiform neuralgia, or so-called incurable facial tic, is a disease characterized by neuralgic paroxysms of great intensity, occurring in one or more branches of the fifth nerve, and usually, if not always, confined to one side of the face. The paroxysms seldom last more than half a minute, and recur with great irregularity, sometimes five or six times an hour, and sometimes not more than twenty or thirty times in the twenty-four hours. They may be determined by a variety of causes, eating, speaking, washing the face, or any peripheral irritation of howsoever trivial a nature. The treatment of this affection has hitherto been eminently unsatisfactory. Nearly every known drug has been tried without effect, the only one that gave even a measure of relief being opium in large and repeated doses. Neurotomy, neurectomy, the introduction of hot needles into the foramina of exit of the different branches of the nerve, and the extirpation of one of the ganglia connected with it have all been employed, but have brought about only temporary freedom from the paroxysms. In an article on this subject in *The Practitioner* for July, 1884, Mr. W. J. Walsham claims to have cured a number of cases by stretching the affected nerve. Three of his patients had previously undergone neurotomy or neurectomy with but temporary relief, while nerve-stretching was followed by the most happy results. The author gives a brief history of each of his cases, promising to publish a more detailed account of them after a sufficient time has elapsed to satisfy him that the cure is a permanent one. Already, at the time of writing, the patients had been relieved of their pain for periods of from three months to three years. In order to reach the inferior dental nerve, the mouth being held open by a gag, an incision is made through the mucous membrane from the last molar tooth in the upper jaw to the last molar tooth in the lower. The finger is now introduced into the wound and insinuated between the ascending ramus of the jaw and the internal pterygoid muscle. The small spur-like projection of bone at the entrance of the inferior dental canal is next felt for and serves as a guide to the nerve. An aneurism needle with a very short curve is now passed and hooked around the nerve, which can be then drawn visibly into the entrance of the wound. The structures in the neighborhood to be avoided are the inferior dental artery and gustatory nerve. It should also be remembered that the internal lateral ligament, which is inserted into the spur-like process of bone, follows somewhat the same course as the nerve, and might be mistaken for it. In order to avoid this it is necessary to hitch the point of the needle in the entrance of the canal, and thence sweep it upward, backward, and outward around the nerve.

Morphine in the Vomiting of Pregnancy.—Dr. W. C. Roberts, of Albany, Wisconsin, writes that in three cases of obstinate vomiting of pregnancy he successfully used muriate of morphine per rectum in half-grain doses. Dr. Roberts asks for the experience of others with morphine given in this way.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 30, 1884.

SPERMATOPHOBIA AND SPERMATORRHŒA.

IF we may except the able treatise of Bartholow, no recent publication has handled with more good sense and fairness than the little work of Malécot[1] a disease which is oftener to the patient a terrifying phantom of the imagination than an actuality, but which, whether fanciful or real, is certain continually to try the patience and skill of the busy practitioner.

Malécot has the merit of showing that the "classical tableau" of symptoms, so strikingly set forth by Lallemand in his too influential work published in 1840,[2] and since then adopted and improved by many well-meaning writers (to say nothing of the harvest-field which this "tableau" has been for quacks in all lands), is found, when subjected to a rigorous criticism, to have little foundation in fact, being the result of "ignorance of the pathology of the genito-urinary organs," and a "superficial diagnosis, devoid of scientific precision." Led astray by a preconceived idea, neglecting—what is assuredly of the utmost importance in diagnosis—the helpful guidance of the microscope, these writers, from Lallemand downward, have attributed to seminal losses (which either did not exist at all, or were physiological) symptoms which "were the consequence of affections of the passages, to-day well understood, such as chronic urethritis, cystitis, prostatitis, or urinary tuberculosis." Those, moreover, who are familiar with Lallemand's book know that he dwells much on certain morbid appearances of the urine—turbidity, flocculence, glairy sediments, etc. —as indicative of the presence of sperm! Even Trousseau, through deference to Lallemand's authority, committed the same error; he placed much stress on the presence in the urine of certain "granulations, and brilliant corpuscular bodies," on which Lallemand also insisted.[3] These "granulations" and "corpuscles" have been invariably found by Malécot to be formed of "bladder epithelium and pus globules, enveloped in a reticulum of fibrine; spermatozoids were absent."

Certain urethral discharges having been shown to be not seminal, and of little prognostic value, how shall we account for the accompanying symptoms which, divested of the usual exaggerations, are those of spinal erethism —of so-called "nervous irritability" or "debility," with consequent depression of the principal visceral functions? One of three suppositions will explain all of these cases, so familiar to every physician. Either the neurotic symptoms are quasi-accidental accompaniments of the bladder or urethral troubles, being dependent on some common cause producing functional nervous disturbance, as overwork—mental or physical—alcoholism, or some other vice; or they are the expression of some pathological affection of the brain or spine—an extremely frequent antecedent of the ills usually attributed to seminal losses; or else they are the results of the local catarrhal states, through the mysterious but well attested influence of the emotions and the imagination on the nervous system and the organic processes. The latter division will embrace all the victims of what Malécot rather infelicitously calls "physiological spermatorrhœa;"—young men who make extravagant account of their occasional seminal losses, and whose habitual emotional frame favors an erethistic condition of the genital organs, and of whom it may be affirmed that there is nothing the matter with them but *spermatophobia*. This latter word is so good and so apposite that it might almost be used to indicate a definite pathological syndrome, with whose outlines every physician is acquainted. Many of these unhappy persons are veritable hypochondriacs, "always preoccupied with their health, attaching an excessive importance to the least urethral discharge, whatever may be its nature;" fatiguing by their prolixity their medical attendant, who vainly endeavors by reason or by banter to rid them of their delusion.

A word of caution is here necessary; these patients are often real sufferers. If the occasional losses, urethral, prostatic or seminal, are of little or no detriment *per se*, the state of mind known as *spermatophobia* is an actual psycho-cerebral disease, akin to melancholia or the delirium of persecution. In fact, one of the cases (Obs. xvi.) reported by Malécot as "imaginary spermatorrhœa" concerns a patient who was clearly a victim of mental alienation, bordering on the *delirium of persecution*. Several cases of insanity cited by Lallemand as consecutive to seminal losses are also instances of the same kind, the insane neurosis, developed to activity, not by spermatorrhœa, but by spermatophobia. Another evil is likely to result from the intense concentration of the attention on certain organs and organic states, which is characteristic of this class of patients. By a law of nervous function, not yet well understood, the very evil which is dreaded may be engendered, and what Malécot calls "physiological spermatorrhœa" may end in the pathological kind. As means to this end we need only to refer to the well-known effect, on certain ill-balanced minds, of the perusal of a class of books, unfortunately too prevalent, and sensational advertisements (from which good newspapers are not always free), published in the interest of quackery, and appealing to all who would not wish, in the flower of their youthful days, to part with their manhood and their vitality.

One point has been clearly shown in the treatise of Malécot, namely, that the facts of the disease under consideration have been understood and interpreted differently as they have been studied by physicians or by surgeons. Surgeons have devoted their attention too exclusively to the genito-urinary apparatus, regarding the disease as a local affection and demanding local treat-

[3] Trousseau: De la Spermatorrhèe. Paris, 1867.

ment; physicians have emphasized the constitutional aspect, seeing in spermatorrhœa only a disease of the nervous system. The latter view seems to be the correct one. It is now very generally admitted that true spermatorrhœa as the result of urethral inflammations, of an over-sensitive urethra in the vicinity of the *vera montanum*, of "atony of the ejaculatory ducts," does not exist. "To-day the hypothesis of a sort of mysterious spermatorrhœa, supervening without ejaculation, by paralysis, by want of contractility of the ejaculatory ducts, cannot longer be maintained. The labors of Cadeat and Robin have shown that while the vas deferens is provided with muscular fibres, the ejaculatory ducts are altogether destitute of any muscular coat, being constituted of elastic fibrous tissue. Despite their name, then, they take no active part in the phenomenon of ejaculation. The presence of sperm in the urethra seems to be due to an overflow of the vesiculæ seminales, too great fulness of those diverticula overcoming by pressure the resistance of the ejaculatory canals." [1]

The division into *true* and *false* spermatorrhœa, adopted by Carlie in "Quain's Dictionary of Medicine," is more sensible than that of Malécot, who considers the subject under three heads: *physiological, imaginary,* and *pathological;* the two first divisions corresponding to Quain's false spermatorrhœa. Under the head of *physiological,* however, Malécot includes cases which are really morbid, *i.e.,* the pollutions are in excess and attended with debility, owing to erethism of the whole genito-spinal nervous apparatus; there is no doubt moreover that this genito-spinal excitement is very frequently the result of abuses of the sexual function. Patients of this kind are always benefited by marriage and moderate indulgence. True spermatorrhœa or loss of seminal fluid without erection or without sexual desires is a malady fortunately as rare as it is formidable. It is not an idiopathic affection, but is dependent on and symptomatic of certain morbid states of the cerebro-spinal axis. Venereal excesses and genital affections are only predisposing, not efficient causes, and the subjects of this disease are by inheritance neuropathic. The reflex shock, of which the pollution is the final expression, may lead to more or less exhaustion of the nervous centres, the fright and anxiety occasioned by the nocturnal losses may have a powerfully depressing influence, but the loss of semen is of no consequence whatever, it is certainly not the cause of the nervous disturbance and the prostration.

There are certain morbid conditions of the cerebrum which are an efficient cause of spermatorrhœa. Venereal excesses, as well as involuntary pollutions, are often the first symptoms of mental alienation and of general paralytic dementia, perhaps from lesion (as Ferrier supposes) of a special sexual centre in the cortex. There are certain monstrous aberrations of the sexual appetite described in works on insanity under the heads *necrophily, lycanthropy,* etc.; onanism, satyriasis, and nymphomania are sometimes noted in confirmed hysteria and epilepsy. But it is especially in irritative affections of the spinal marrow that we observe true spermatorrhœa; and Trousseau and Charcot have both pointed out the frequency of this disease in the early stages of locomotor ataxia. Much, however, is yet needed to complete our knowledge on this subject.

"PASTEURIZATION" AGAINST HYDROPHOBIA.

RECENT reports from Paris show that M. Pasteur has undoubtedly scored another success in his scientific work. The Commission, consisting of MM. Béclard, Paul Bert, Buclez, Tisserand, Villemain, Vulpian, and Bouley, appointed to investigate M. Pasteur's claims for the discovery of a protective vaccine against rabies, has made its report. The members have gone over Pasteur's experiments and found that without question he has been able to protect dogs against all inoculations with hydrophobic virus. A new truth is born to science, therefore, viz.: One attack of hydrophobia or of modified hydrophobia protects against another. For this alone Pasteur deserves the greatest credit. But the query next arises, Will the discovery be of any value? This depends mainly upon the question whether inoculation with the vaccine after a person is bitten will furnish an efficient protection. It is reported that Pasteur has tried this already in one case and with success. But the Commission refrain as yet from expressing a decided opinion. They will "continue their labors." Meanwhile M. Pasteur has suggested a plan of protecting the human race against rabies in case that the vaccine fails to work after a person is bitten.

This plan consists in nothing else than the compulsory "Pasteurization" or protective inoculation of all the dogs in the country, just as infants are compulsorily vaccinated. The project is a very comprehensive one, but by no means easy to carry out, in view of the large number of dogs and the rapidity with which they multiply. Besides, society must adjust its protective labors to sufficient ends. Hydrophobia is a fearful disease, but a rare one.

Perhaps one dog in a million gets it. In the whole o the United States there occurred in 1860 only 38 deaths from hydrophobia; in 1870 only 63 cases. In New York City the number of deaths from rabies between the years 1855 and 1874 was 57, the annual number ranging from 0 to 4. In England the annual mortality has of late years ranged from 20 to 50. In France hydrophobia kills about 200 persons a year.

But while the disease is a small element in mortality generally, it sometimes appears to become almost epidemic in activity. It is in such cases and under such circumstances that "Pasteurization" might perhaps wisely be enforced.

THE PROPOSED GROSS MEMORIAL PROFESSORSHIP.

WE have received some protests against the views expressed regarding the proposed memorial professorship to the late Professor Gross. We should be very sorry to have our meaning and position misunderstood, as evidently has been done. No one deserves a greater or more honorable memorial than the late Professor Gross, and for this very reason we protested against the founding a professorial chair in a private medical college, as a petty and inadequate act of commemoration. After the

chair is established, only medical students and readers of the annual catalogue will hear of it. Professor Gross' life deserves a grander and more conspicuous monument. We regret, therefore, that the committee having the matter in charge did not make a wiser choice. Already signs of dissatisfaction are being shown among the physicians in the West. Let the committee take advice that is most sincerely meant. It cannot "boom" a project to give Jefferson Medical College one hundred thousand dollars, although that is a most worthy institution. It can, however, by a very slight change, make its proposed chair of pathology a public lectureship on pathology or some allied subject, for the benefit of physicians. Such lectureships as in England annually commemorate the names of Harvey, Hunter, Lettsom, Gulston, and others, would fittingly adorn the memory of America's greatest surgeon.

THE PARISIAN AND THE BERLIN VIEW OF THE COMMA-BACILLUS, OR SPIRILLUM.

At the cholera conference in Berlin, of which we give an account elsewhere, Dr. Koch has described to a sympathetic audience his comma-bacillus, and given his most cogent reasons for believing it to be the true cause of the cholera.

Almost at the same time M. Strauss, at the Académie de Médicine of Paris, gives to an even more sympathetic audience the reasons why he thinks the comma-bacillus is not the specific organism of cholera. He states that, in connection with M. Roux, eighteen autopsies were made upon cholera patients at Toulon. In the *foudroyant* cases the comma-bacillus, or as Koch is now inclined to call it, the "spirillum," was found abundantly; but "in the subacute cases it was impossible to detect their presence." Further, Strauss says: "In a good number of cases of cholera one does not find micro-organisms in the intestinal tunics."

To strengthen his argument still more, M. Strauss says that Dr. Maddore, of Tendres, has photographed a comma-bacillus which he has found in a reservoir of water; that M. Malassez has shown him (Strauss) bacilli of comma shape obtained from dysenteric stools. M. Strauss had himself seen comma-bacilli in the vaginal mucus of women suffering from leucorrhœa, and in the uterine secretion of a woman suffering from epithelioma of the neck.

Although M. Strauss' remarks were received with much favor by the learned Académie, his argument appears to us to be disingenuous and weak. It contrasts most unfavorably with the vigorous exposition of his views made by Dr. Koch, in whom we are more than ever inclined to feel confidence.

AMERICAN JOURNALISTIC ENTERPRISE.

For four successive issues THE MEDICAL RECORD has contained reports by cable of the proceedings of the two most notable medical gatherings of the year. We have thus been able to present the main features of these meetings to our readers even sooner than they were known to the profession in Europe. It will be a matter of some pride to our American readers, as it naturally is to ourselves, that in journalistic enterprise THE RECORD has so far outstripped all previous efforts. THE RECORD was the first medical journal to use the Atlantic cable, and we can safely say that its cabled reports have far exceeded in number and length those attempted anywhere else. Our readers would, we are sure, excuse this small attempt at self-praise, if they knew the amount of extra labor, calculation, and expense involved in these efforts to present promptly and accurately the medical work of the day.

News of the Week.

THE AMERICAN MICROSCOPICAL SOCIETY held its annual meeting last week at Rochester, N. Y.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.—The eighth annual session of the American Dermatological Association took place this week at West Point, N. Y.

MEDICAL SOCIETY OF NORTHERN NEW YORK.—The Fall Meeting of the Medical Society of Northern New York will be held at the City Hall, Albany, Wednesday October 1, 1884.

THE CHOLERA has continued to spread through the provinces of Southern France and Northern Italy, and has even invaded Switzerland. Its progress has been of late more rapid and its manner of attack more violent. Thus in the Western Pyrenees it spread to thirteen places within a week. In Italy it suddenly attacked La Spezia on August 22d. In three days there had been 79 deaths. The correspondent of the *New York Times* telegraphs that up to August 23d there had been 3,952 deaths from cholera in Southern France. These deaths were distributed among one hundred and thirty-one cities and villages, in fifteen departments. Up to August 15th the disease had attacked only fifteen places. In the next week it had spread to fifty-one new places. In Italy the number of deaths already is about four hundred, and this number is being increased daily. The number of provinces affected is six.

SUICIDE OF THE LATE DR. J. J. WOODWARD.—It is known that the late Surgeon Woodward, U.S.A., was insane at the time of his death, and confined in a private asylum. There seems to be little doubt now that the unfortunate man met his death by his own hands. An account states that he had been under care for about four months, but at no time was violent or in any way troublesome. He generally preferred to be let alone, and evinced a delicacy in having any intrusion upon his privacy. Though of a strong and healthy physique, he imagined himself of a delicate constitution. He was as regular as clockwork in his habits, and among the best patients in the home. On Sunday morning he was passed on the stairway by one of the lady attendants, who saw him on the edge of the porch roof. A few minutes later, before anything could be done to rescue him, he threw himself off the roof backward, falling on the steps below, receiving injuries from which he died on the afternoon of the same day.

DEATH OF DR. BURQ, THE METALLO-THERAPEUTIST.—The death is announced of Dr. Burq, of Paris, aged sixty-two. Dr. Burq's name has been made very familiar to the medical world by reason of his persistent efforts to gain a scientific standing for metallo-therapy. This he had succeeded in doing, at least in France. Of late he had been urging the prophylactic value of copper against

cholera. He had just received a mass of testimonials from mining engineers, bronze and copper manufacturers, doctors, and Sisters of Charity in favor of his copper theory. He even held a letter from a doctor who said that he had, after gargling his throat with a solution of salts of copper, sucked with impunity diphtheritic matter from a child in whose windpipe he had made an incision. Dr. Burq was rejoicing in the idea that, owing to M. Bert's influence, the Municipal Council in future would cause all wood employed in the hospitals to be steeped in cupric solution.

Death of Dr. C. W. Chamberlain.—Dr. Charles Walter Chamberlain, Secretary of the State Board of Health of Connecticut, and a member of the National Board of Health, died in Hartford on August 21st. Dr. Chamberlain was born in Providence, R. I., July 22, 1844, and was a son of the Rev. Charles Chamberlain. He was educated at Brown University, and the College of Physicians and Surgeons in this city, graduating from the latter institution in 1871. He made a specialty of laryngology, and established himself in Hartford. He was Secretary of the State Medical Society in 1876, and contributed to the Transactions of that year two papers upon throat disease, and in the following year a third paper on a similar subject. In 1877 Governor Hubbard appointed Dr. Chamberlain Examining Surgeon for the soldiers in the State hospitals. He was also for a number of years Examining Surgeon to the United States Pension Bureau, and was well known throughout the country as a distinguished sanitarian.

The Late Dr. Burq, the Copper Specific, and Pasteur.—The Paris correspondent of the London *Truth* writes: "And now a little benevolent gossip about the arch-enemies of the Cupric Saviour. Burq, 'fortified' by his medicament, has been since 1849, during every cholera visitation, in the hospitals of the towns where it was most virulent. He faced it at Toulon and Marseilles, in Paris, Rouen, London, and Eastern France. He also faced smallpox in its worst haunts. Pasteur only studies these maladies at a distance. A little virus is brought to him in a glass tube, and then he operates with it upon apes, monkeys, dogs, and guinea-pigs. He preaches *ex cathedrâ*, and all the cowards who are afraid of losing their worthless lives, and who cannot bear to think that fair play should be the great sweetener of the world and reign everywhere, laud him as a benefactor of the human race and a stamper-out of plague and pestilence. When a contagious disease burns itself out in a place where some mitigated virus has just produced as good an effect as Lourdes water, they cry out, 'Great is Pasteur!' He reminds me of Vain-Hope, the ferryman in the 'Pilgrim's Progress,' who saved people the trouble of wading through the river which lay between the land of Beulah and the Celestial Kingdom. Poultry-yard cholera, ovine carbuncle, murrain, rinderpest, smallpox, scarlatina, and every other curse upon dirt and gluttony are as severe as ever, and yet the notion is abroad that Pasteur, through his scapegoat animals, has taken the sting out of them all. Pasteur, who has not gone to Marseilles to correct or to check the theories he builds up in his torture-house in the Rue d'Ulm, has got himself appointed French Commissioner to the Health Congress which is to be held at Amsterdam. I don't at all try to convey the idea that he is a humbug. He believes in his theories, and has got to look upon himself as a divinity. When his son-in-law wrote that 'Te Pasteurium Laudamus' ('Monographe de Pasteur par un Ignorant') in one volume, the object of the praises himself corrected the proofs! Pasteur is a priest who lives by the altar. He has 25,000f. a year from the State to enable him to pursue his researches, with lodgings, coal, and lamplight, and is soon to have a delicious country residence at Villeneuve l'Etang, where a dogs' Inferno is being created for him. His mitigated viruses are a source—and a good one—of income. He has married his daughter advantageously; through Brown-Séquard's and Paul Bert's manias for vivisection *à outrance* he is on good terms with the Opportunists, and owing to his unmitigated clericalism he enjoys the friendship of the dukes and counts at the Academy. If a king starts up, he will have access to him; if the republic continues, he will go on drawing his 25,000f. a year. His son-in-law (the author of the 'Te Pasteurium Laudamus') was, a few years ago, a secretary to M. de Freycinet. It is on the cards that he may hereafter receive royal dukes at Albert Gate House."

Dr. Koch's Berlin Lecture on Cholera and the Comma-Bacillus.—An important conference upon cholera was held in Berlin, at the Imperial Board of Health, on the evening of July 26th. There were present Drs. Von Bergman, Coler, Eulenberg, B. Fränkel, Gaffky, Hirsch, Koch, Leyden, S. Neumann, Pistor, Schubert, Skreczka, Struck, Virchow, and Wolffhügel. The conference had been called at the instance of the Berlin Medical Society, whose President, Professor Virchow, explained that it was thought advisable Dr. Koch should in the first instance give a demonstration of his work before a smaller body than the whole Society, so that the proceedings might be fully reported in the medical press. He mentioned that Herr Director Lucanus and President Sydow had expressed their regret at being unable to be present, as well as many others, including Drs. Von Lauer, Von Frerichs, Mehlhausen, and Kersandt. Dr. Koch first showed various specimens of the bacillus and their method of preparation (see *Berliner Klinische Wochenschrift*, August 4th). This resembles that for the tubercle bacillus, viz., drying on a cover-glass and staining with fuchsin or methyl-olin. Koch then gave a history of his work while in Egypt and India. His post-mortem examinations led him to believe that the intestines were the nidus of the disease. At first his microscopical examinations were unsatisfactory, but finally he got fresh dejecta and acute cases, and then discovered the comma-bacillus.

This, he said, is smaller than the tubercle bacillus, being only about half or at most two-thirds the size of the latter, but much more plump, thicker, and slightly curved. As a rule, the curve is no more than that of a comma (,), but sometimes it assumes a semicircular shape, and he has seen it forming a double curve like an S; these two variations from the normal being suggestive of the junction of two individual bacilli. In cultures there always appears a remarkably free development of comma-shaped bacilli. These bacilli often grow out to form long threads, not in the manner of anthrax bacilli, nor with a simple

undulating form, but assuming the shape of delicate long spirals—a corkscrew-shape—reminding one very forcibly of the spirochæte of relapsing fever. Indeed, it would be difficult to distinguish the two if placed side by side. On account of this developmental change, he doubted if the cholera organism should be ranked with bacilli; it is rather a transitional form between the bacillus and the spirillum. Possibly it is true spirillum, portions of which appear in the comma shape, much as in other spirilla—*e.g.*, spirilla undula, which do not always form complete spirals, but consist only of more or less curved rods. The comma-bacilli thrive well in meat infusion, growing in it with great rapidity. By examining microscopically a drop of this broth culture the bacilli are seen in active movement, swarming at the margins of the drop, interspersed with the spiral threads, which are also apparently mobile. They grow also in other fluids—*e.g.*, very abundantly in milk, without coagulating it or changing its appearance. Also in blood serum they grow very richly. Another good nutrient medium is gelatine, wherein the comma bacilli form colonies of a perfectly characteristic kind, different from those of any other form of bacteria. The colony when very young appears as a pale and small spot, not completely spherical as other bacterial colonies in gelatine are wont to be, but with a more or less irregular, protruding, or jagged contour. It also very soon takes on a somewhat granular appearance. As the colony increases the granular character becomes more marked, until it seems to be made up of highly refractile granules, like a mass of particles of glass. In its further growth the gelatine is liquefied in the vicinity of the colony, which at the same time sinks down deeper into the gelatine mass, and makes a small, thread-like excavation in the gelatine, in the centre of which the colony appears as a small white point. This, again, is peculiar; it is never seen, at least so marked, with any other bacterium. And a similar appearance is produced when gelatine is inoculated with a pure culture of this bacillus, the gelatine liquefying at the seat of inoculation, and the small colony continually enlarging; but above it there occurs the excavated spot, like a bubble of air floating over the bacillary colony. It gives the impression that the bacillus growth not only liquefies the gelatine, but causes a rapid evaporation of the fluid so formed. Many bacteria also have the power of so liquefying gelatine with which they are inoculated, but never do they produce such an excavation with the bladder-like cavity on the surface. Another peculiarity was the slowness with which the gelatine liquefied, and the narrow limits of this liquefaction in the case of a gelatine disc. Cultures of the comma-bacillus were also made in Agar-Agar jelly, which is not liquefied by them. On potato these bacilli grow like those of glanders, forming a grayish-brown layer on the surface. The comma-bacilli thrive best at temperatures between 30° and 40° C., but they are not very sensitive to low temperatures, their growth not being prevented until 17° or 16° C. is reached. In this respect they agree with anthrax bacilli. Koch made an experiment to ascertain whether a very low temperature not merely checked development but killed them, and subjected the comma-bacilli to a temperature of —10° C. They were then completely frozen, but yet retained vitality, growing in gelatine afterward. Other experiments, by excluding air from the gelatine cultures, or placing them under an exhausted bell-jar, or in an atmosphere of carbonic acid, went to prove that they required air and oxygen for their growth; but the deprivation did not kill them, since on removing them from these conditions they again began to grow. The growth of these bacilli is exceptionably rapid, quickly attaining its height, and after a brief stationary period as quickly terminating. The dying bacilli lose their shape, sometimes appearing shrivelled, sometimes swollen, and then staining very slightly or not at all. The special features of their vegetation are best seen when substances which also contain other forms of bacteria are taken—*e.g.*, the intestinal contents or choleraic evacuations mixed with moistened earth or linen and kept damp.

A most important statement was that the comma-bacillus seems to be killed by the bacteria of putrefaction, and consequently agents that destroy the latter organisms without the former may really do injury, by removing from the cholera bacillus an impediment to its growth. As for destructive agents to the bacillus, he found it killed by solutions in the following proportions: oil of peppermint, 1 in 2,000; sulphate of copper, 1 in 2,500 (a remedy much employed, but how much would really be needed merely to hinder the growth of the bacilli in the intestine!); quinine, 1 in 5,000; and sublimate, 1 in 100,000. In contrast with the foregoing measure for preventing the growth of these bacilli is the striking fact that they are readily killed by drying. This fact is proved by merely drying a small drop of material containing the bacilli on a cover-glass, and then placing this over some of the fluid on a glass slide. With anthrax bacilli vitality is retained for nearly a week; whereas, the comma-bacillus appears to be killed in a very short time.

Dr. Koch having found and cultivated the comma-bacillus, and ascertained its distinctive character, next proceeded to investigate its relation to cholera. In all there were now about one hundred cases of cholera in which the bacillus had been found, while it was never found in connection with other diseases. Three different views, said the speaker, as to its relation to the cholera process are tenable. 1. That the disease favors the growth of these bacilli by affording them a suitable soil. If so, it would mean that the bacillus in question is most widely diffused, since it has been found in such different regions as Egypt, India, and France; whereas the contrary is the case, for the bacilli do not occur in other diseases, nor in the healthy, nor apart from human beings in localities most favorable to bacterial life. They only appear with the cholera. 2. It might be said that cholera produces conditions leading to a change in form and properties of the numerous intestinal bacteria—a pure hypothesis; the only instance of such a conversion refers to a change of physiological and pathogenic action, and not of form. Anthrax bacilli under certain conditions lose their pathogenic power, but undergo no change in shape; and that is an instance of a loss of pathogenic properties, while there is no analogy to support the view of the harmless intestinal bacteria becoming the deadly cholera bacilli. The more bacterial morphology is studied, the more certain is it that bacteria are constant in their form; moreover, the comma-bacillus retains its special characters unchanged through many generations

of culture. 3. Lastly, there is the view that the cholera process and the comma bacilli are intimately related, and there is no other conceivable relation but that the bacilli precede the disease and excite it. "For my own part," said Dr. Koch, "the matter is proved that the comma-bacilli are the cause of cholera."

Dr. Koch then described his attempts to inoculate lower animals with the bacillus, and explained the cause of his failure in the natural immunity of the animals against the disease.

In advocating the local Indian origin of the disease he said: That the virus can be reproduced and multiplied outside the body is apparent, since the bacillus can be cultivated artificially, and its growth is not affected by comparatively low temperatures. Probably it does not grow in streams and rivers, where, owing to the current, a sufficient concentration of nutrient substance does not occur; but in stagnant water and at the mouths of drains, etc., vegetable and animal refuse may accumulate and afford the necessary nutriment. Thus is explained the propagation of cholera by the subsoil water, and the increase of epidemics with the sinking of its level, which lessens the flow and diminishes the amount of surface water. Admitting the dependence of cholera upon this micro-organism, it is impossible to conceive the disease having an autochthonous origin in any particular place; for a bacillus must obey the laws of vegetable life, and have an antecedent; and since the comma bacillus does not belong to the widely diffused micro-organisms, it must have a limited habitat. Therefore, the occurrence of cholera on the delta of the Nile does not depend on its resemblance to the delta of the Ganges; but the disease must have been imported there as it is into Europe. It was once thought that an outbreak in Poland had a local origin until it was discovered to have been introduced from Russia. Again, about ten years ago, there was a sudden outbreak at Hamar (Syria), thought to be an instance of local origin, but erroneously, as shown by a statement of Lortet, who told Koch, when at Lyons, that the epidemic had been introduced into Hamar, where he was at the time, by Turkish soldiers from Djeddah. All great epidemics of cholera began in South Bengal, where the conditions for the development and growth of the bacillus are most perfect.

Dr. Koch concluded with a reference to the prospective practical value of his discovery. It would assist in leading to intelligent prophylaxis and treatment, and in making an early diagnosis.

At the close of his lecture a discussion took place, which we shall report in our next issue.

Pleuro-pneumonia in the West.—A herd of Jersey cattle infected with pleuro-pneumonia were sold at auction recently, and the disease was thus disseminated through several herds in Illinois, and perhaps other States. The condition of affairs is serious, though incomparably less so than if the disease had reached the great herds of beef cattle of the West instead of smaller herds of registered cattle.

A Philanthropic Surgeon.—The late Sir Erasmus Wilson was one of the few doctors who are both able and willing to give. Sir Erasmus distinguished himself by many benefactions. He founded a chair and a museum of dermatology, and a chair of pathology, built a master's residence at Epsom College, and part of a sea-bathing hospital at Margate. He brought Cleopatra's Needle to England at an expense of $50,000, so that the obelisk may properly be considered a surgeon's needle, and he gave away a great deal of money in private benefactions.

Hog Cholera has been prevailing since last winter in certain counties of New Jersey.

Druggists' Conventions. — The second annual meeting of the National Druggists' Association was held at Milwaukee, Wis., August 25th and 26th. This is the association which aims to promote the "Campion plan" for keeping up prices and cutting off the "scalpers." During the past year it is claimed to have been partially successful. The Association numbers about twenty-five hundred members.

On August 26th, the National Pharmaceutical Association convened in the same city.

Obituary.

THE LATE SURGEON J. J. WOODWARD, U.S.A.

War Department,
Surgeon-General's Office,
Washington, D. C., August 20, 1884.

In announcing to the officers of the Medical Department the death of Joseph Janvier Woodward, Surgeon and Brevet Lieutenant-Colonel U. S. A., which occurred near Philadelphia, Pa., August 17, 1884, the Surgeon-General wishes to offer his tribute of respect to the memory of the deceased, whose distinguished career and valuable services for a period of twenty-three years have shed lustre on the corps, and for whose untimely loss feelings of profound regret will be shared alike by his comrades in arms and by the profession at large.

Dr. Woodward was born in Philadelphia, Pa., October 30, 1833, and was educated at the Central High School of that city, graduating with honor as Bachelor of Arts in 1850, and receiving the degree of Master of Arts from the same institution in 1855.

He graduated in medicine at the University of Pennsylvania, April, 1853; entered the Army as Assistant Surgeon, August 5, 1861; became Captain and Assistant Surgeon, July 28, 1866; Major and Surgeon, June 26, 1876. "For faithful and meritorious services during the War" he received the brevets of Captain, Major, and Lieutenant-Colonel U. S. A.

He was assigned to duty in this Office May 19, 1862, and from that date until the beginning of the illness which terminated in his death was intimately identified with its professional and scientific work.

While the valuable results of his life's labor are comprehended in a long list of miscellaneous publications, both professional and scientific, too familiar to the corps to require individual mention, his greatest triumphs were won in the field of microscopical investigation in normal and pathological histology, and in his happy application of photo-micrography to the purposes of science. In these pursuits he attained remarkable success, and achieved an enviable, world-wide reputation, leaving to science and medicine lessons of undoubted value and usefulness. Of his strictly professional work the medical portion of the "Medical and Surgical History of the War of the Rebellion" was the crowning achievement. In the second part of this work he developed the results of his careful investigations into the nature and pathology of the intestinal diseases which had proved so fatal in the

late war. Here also he displayed his wonderful capacity for that minute and exhaustive research which forms so striking a feature of his writings.

As in the case of his co-laborer, Otis, he yields to other hands the honor of completing his labors.

In addition to his engrossing professional duties, his restless activity of mind led him to seek recreation in his favorite studies—physics, art, and philosophy.

Endowed with a retentive memory and of untiring industry, he acquired a vast store of information which he held available for use at will; fluent of speech, he took delight in the expression of his views and opinions both in social converse and in the arena of scientific debate.

His fund of knowledge, his strong convictions, his tenacity of opinion, and his quick perception made him a controversialist of no low order.

With such a record, it is needless to speak of his zeal, his ambition, or his devotion to his profession, and especially to the reputation of the corps of which he was so bright an ornament.

Of a sensitive, highly strung, nervous organization, the confinement, anxiety, and labor to which he was subjected in his attendance upon the late President Garfield during his long illness, proved too much for a mind and body already overstrained by incessant labor, and precipitated the illness which finally terminated his life.

At the time of his death Dr. Woodward was a member and ex-President of the American Medical Association, a member and ex-President of the Washington Philosophical Society, a member of the National Academy of Science, of the Association for the Advancement of Science, of the Academy of Natural Sciences of Philadelphia, and of the College of Physicians and Surgeons of Philadelphia. He was an honorary member of several American and foreign scientific, medical, and microscopical societies, and the recipient of many distinguished honors from learned bodies in this country and abroad.

R. MURRAY,
Surgeon-General U.S.A.

Reviews and Notices.

TRANSACTIONS OF THE AMERICAN GYNECOLOGAL SOCIETY. Volume VIII. For the Year 1883. New York: D. Appleton & Co. 1884.

WE have not sufficient space allowed us to attempt a critical review of this interesting volume. We can only furnish to the general reader some indications of its contents. We would say, in the first place, however, that the papers and discussions are quite up to the high general average, and express better than do most society transactions, the views of America's leading specialists in gynecology. On the whole the papers have a more general interest than is the case with much other specialistic work.

A perusal of the volume before us shows that the gynecologists continue to entertain a healthy difference of opinion upon some of the elementary points in their specialty. For example, Dr. Emmet describes a new operation for lacerated perineum, and in one article wipes out all his previous teachings and experience on this subject. We are left finally in doubt whether there is any perineum, and whether, if it exists, it has any function whatever. The well-worn subject of dysmenorrhœa is discussed by Dr. C. D. Palmer, and by Drs. J. R. Chadwick and Fordyce Barker. A few, more or less, new specifics for this trouble are given; such as apiol, cimicifuga, pulsatilla, coca, and ammonia. Perhaps it may be found in time that there is no specific for any form of dysmenorrhœa, but that a great many drugs relieve equally well the same distresses. We are now told that such a thing as mechanical dysmenorrhœa rarely exists. Dr. R. S. Sutton read a paper on "Cleanliness in Surgery" (subsequently read again before the American Academy of Medicine), in which he introduced the subject of "Listerism." Dr. Lusk made an interesting plea for the spray, but gave no very cogent reasons for its retention. Dr. A. Reeves Jackson made an effective argument against the operation for extirpation of the cancerous uterus, which he considered useless and unjustifiable. Dr. George J. Engelmann denounced the excessive use of ergot in obstetric practice, and thought that this drug should only be given in the non-gravid uterus. He exaggerated the dangers and misuses of ergot. Dr. Edward W. Jenks described a new mode of operating for fistula in ano. Dr. Albert H. Smith brought up the subject of "Hot Water in Secondary Hemorrhages after Pelvic Operations." Hot water is all the vogue, and gynecology (which is nothing if not fashionable) commends it in the present volume. Dr. Goodell, to be sure, finds that it is not always potent, and recommends vinegar as an addition.

In the annual address of the President, Dr. Gilman Kimball, attention is called to the life of Dr. Nathan Smith, and to the fact that he independently performed ovariotomy in 1821, knowing nothing of McDowell's operation nine years before.

As regards typographical appearance the volume continues to be the very dude of medical "transactions."

SHAKESPEARE AS A PHYSICIAN: Comprising every Word which in any Way relates to Medicine, Surgery, or Obstetrics found in the Complete Works of that Writer; with Criticisms and Comparison of the Same with the Medical Thoughts of To-day. By J. PORTMAN CHESNEY, M.D. 8vo, pp. 226. Chicago, Ill.; St. Louis, Mo.; Atlanta, Ga.: J. H. Chambers & Co., 1884.

THE title of the above work very clearly indicates its scope and purpose. Beginning with obstetrics, the author gives us quotations from every play containing even remote and incidental allusions to that subject. It is a medical concordance of Shakespeare, with comments and explanations. The author says, no doubt with truth, that his task has not been a slight one. Whether the result is worth the trouble, is a question that will be answered very differently, according to the standpoint of the reader. For our part we are glad to find that doctors occasionally have the taste and inclination to wander a little in the byways and produce some work outside the beaten paths of pathology. Dr. Chesney has done his work conscientiously, and it furnishes a volume of curious interest to the physician. His comments are perhaps the least interesting, and are at times unnecessarily discursive and pedantic; still, not much other than explanation and a superficial exegesis could be expected.

The work is illustrated with a number of curious and more or less appropriate cuts.

A TEXT-BOOK OF THE PRINCIPLES OF PHYSICS. By ALFRED DANIELL, M.A., Lecturer on Physics in the School of Medicine, Edinburgh. London: Macmillan & Co. 1884.

THIS book, says the author, was primarily designed as a contribution to medical education, and as such he hopes it may be found useful. He treats of physics in a very different manner to that in the older works of fifteen or twenty years ago. His book is written strictly from the modern scientific standpoint, and gives the latest and best conceptions of matter and the physical forces.

Some idea of the systematic, yet natural and thorough manner with which the subject is treated, may be gathered from the titles of the chapters. These are in their order: Time, Space, and Mass; Measurements; Work and Energy; Kinematics; Kinetics; Attraction and Potential; Gravitation; Matter; Solids; Liquids; Gases; Heat; Sound, etc.

It would be a great thing for medical students if they were thoroughly disciplined in a work like this. We fear, however, that it would befog the untrained brain of the majority of them.

Reports of Societies.

THE BERLIN SOCIETY OF INTERNAL MEDICINE.

Stated Meeting, July 14, 1884.

HERR LEYDEN, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society having been called to order by the President, HERR KRONECKER exhibited an

APPARATUS FOR THE INFUSION OF SALINE SOLUTIONS

into the general circulation. The speaker stated briefly the principles of this method, which, though by no means a new procedure, was still not so widely known and appreciated as, by reason of its value, it ought to be. There were several precautions to be observed in employing this method for restoring the normal fluidity of the blood, the first and most important of which was to secure a suitable solution. He had formerly thought it important to add a certain proportion of soda to the solution, but had recently omitted the alkali and had obtained equally good results. Experiments on animals had shown that a solution which was suitable for one species might be harmful to another, hence it was not safe to conclude, without further trial, that a mixture which was well borne by certain animals would be suitable for the human subject. Some recent experiments by Aronsohn and Marckwald had shown that a proportion of $\frac{7.3}{100}$ part of chloride of sodium to 100 parts of distilled water (about 56 grains to the pint) caused no irritation to the mucous membranes or subcutaneous tissues, and the speaker proposed a solution of this strength as the one best adapted for intra-venous injection.

Regarding the proper method of introducing the solution into the circulation, Herr Kronecker expressed a decided preference for intra-venous over subcutaneous injection, as offering the greater certainty that the fluid will be taken up by the blood stream. But great care should be observed not to inject the solution too rapidly or with two great pressure, because of the danger of filling the heart with water and driving from it all the blood. Having made a number of observations on this point, the speaker had been able to set five drachms per second as the limit beyond which we should not pass in making intra-venous injections of fluids other than blood. For making the injection we need a bottle, graduated to drachms, to which a rubber tube with canula attachment is fastened. By holding the bottle at a proper height we are enabled to force the fluid at any desired rapidity into the veins; but as the pressure varies according to the amount of fluid contained in the flask, the height at which the latter is held must be constantly raised during the operation. In order to obviate the necessity of this, Herr Kronecker had recently employed a Mariotte flask, by means of which a constant pressure is obtained, whatever may be the variation in the quantity of the contained fluid.

One great advantage possessed by the saline solution was that it could be disinfected. The air in the flask could also be kept perfectly pure by allowing it to pass through cotton saturated with a disinfectant solution.

HERR LEYDEN thought that the question of saline infusions was a timely one in view of the

EPIDEMIC OF CHOLERA

in southern Europe. He hoped that the measures which had been adopted would be effectual in keeping the disease out of Germany. But it was only the part of ordinary prudence to make every preparation to grapple with it should it once gain admittance. He thought that in the event of being called upon to treat cholera the method of intra-venous injections just demonstrated would find a ready application.

HERR S. GUTTMANN thought it would be advisable to appoint a commission to determine just how far transfusion was of value in the collapse consequent upon the loss of fluids in cholera, and also to settle, as far as might be, other points in the prophylaxis and therapy of the disease. Koch's discovery of the parasitic nature of the affection had as yet led to no practical therapeutic results, and we now stood in the presence of cholera just as defenceless as we were a decade ago.

The discussion then turned upon the

PREVENTION AND TREATMENT OF CHOLERA.

HERR FRAENTZEL recalled the fact that it was only during the last epidemic in Berlin that attempts were made to improve the hygienic conditions and that physicians sought to formulate any dietary rules. Since that time considerable advances had been made in these subjects. Experiments had proven the futility of subcutaneous injections of saline solutions, for the tissues would not absorb the fluid, and the only result of an injection was the formation of a tumor, which disappeared only after the lapse of considerable time. He did not deny, however, that intra-venous injections might prove more useful.

The speaker regretted the fact that less attention was now paid to the subject of disinfection than formerly. He called attention also to the danger from mill-streams which contained large quantities of filth and decomposing matters, and he hoped that some measures would be taken looking to their purification.

HERR P. GUTTMANN had made a trial of the infusion of saline solutions during the epidemic of 1866, but all the patients so treated died. He did not believe the cholera would reach Berlin this year, but promised, in case it did, to make further trials with the method just demonstrated. He insisted upon the necessity of removing all cholera patients to a special hospital, since, were they treated in all the hospitals throughout the city, there would be created so many additional foci of disease.

HERR LOEWENSTEIN did not anticipate any brilliant results in the treatment of cholera by saline injections. Restorative measures were needed, and unless it were shown that saline infusions exerted an analeptic action upon the heart, he could not place any dependence upon them.

HERR GUTTSTADT spoke of the danger of rectal injections in cholera, as any irritation of the mucous membranes was liable to excite a diphtheritic inflammation.

HERR LEYDEN thought, notwithstanding the general opposition to saline injections, that possibly, owing to new methods of preparation and perfected apparatus, this mode of treatment might eventually be found useful.

A cholera commission was then appointed, consisting of Herren P. Guttmann, Baer, Goltdammer, S. Guttmann, Lehnert, Riess, and Wernich.

HERR P. GUTTMANN then read a paper upon

ANTIPYRIN.

A number of remedies had recently been made by synthetic processes, which, in suitable doses, possessed a febrifuge action. They were all derivatives of, or closely allied to, chinolin. One of these substances was antipyrin, chemically known as dimethyloxychinicin. It is freely soluble in water and alcohol, possessing a slightly bitter taste, and exists in the form of a powder of a whitish color faintly tinged with yellow. One of its most valuable properties is its great solubility (seven grammes of antipyrin dissolving in three grammes of water), thus rendering it especially adapted for hypodermic use. The author had employed the remedy in a large number of cases of typhoid fever, pneumonia, pulmonary phthisis, measles, scarlatina, and other diseases marked by a high degree of fever. He had found in every instance that the exhibition of a drachm to a drachm and a half of an-

tipyrin, in half-drachm hourly doses, reduced the temperature curve for at least five or six hours, and sometimes for a still longer period. The drug may also be given in a single large dose of a drachm, or in fifteen-grain doses five times repeated, with similar beneficial effects. The dose for children is seven grains frequently repeated.

When half-drachm doses are given, the temperature begins to fall even during the first hour, but reaches its lowest point at the end of the third or fourth hour. The minimum reduction observed by the author was 1° F., and the maximum 7°. The temperature begins to rise again about an hour after the last dose is taken, but the ascending curve is so very gradual that it is usually ten or twelve hours before the remedy need be again exhibited. There are no unpleasant symptoms produced; with the occasional exception of vomiting. The only pyretic condition over which antipyrin exerts no effect is intermittent fever, though even here the paroxysm seems to be less severe if a full dose of the drug has been given before its onset.

The febrifuge action of antipyrin is only one-half as powerful as that of quinine, that is, it requires one drachm of the former to produce the effect obtained by thirty grains of the latter. Unfortunately at present antipyrin costs two-thirds as much as quinine, hence it cannot be recommended on account of its cheapness. When it becomes possible to lower the cost of its production, it will rank as a febrifuge much preferable, in most cases, to quinine.

Herr Tillmanns had employed antipyrin in a number of cases with success at the Charité clinic. In eight cases of intermittent fever he had cut short the paroxysms by antipyrin, but immediately upon the discontinuance of the remedy the temperature rose again. He had found the drug of especial value in the pyrexia of phthisis. In typhoid fever the patients expressed themselves as feeling much better after taking half-drachm doses of antipyrin, and the drug seemed also to exert a controlling effect upon the diarrhœa. The antipyretic action of the drug was in every case prompt and certain, and was accompanied, especially in phthisis and pneumonia, by a rather profuse perspiration. No injurious effects were ever observed.

In conclusion, the speaker stated that the results obtained by him were in accord with those of the author of the paper. He would, however, advise beginning the administration of antipyrin by small doses (10–15 grains or less), which could then be increased if necessary. This caution should specially be heeded in phthisis, as he had seen rather alarming symptoms of collapse follow the exhibition of large doses.

On motion, the Society then adjourned.

Irreducible Hernia Cured by Sneezing.—Dr. John Burke, of this city, sends us the history of a man, aged sixty, who had suffered for several years from an irreducible left inguinal hernia. Several surgeons had tried to get it back, but in vain, and the tumor became as large as a child's head. One night he was attacked with a fit of coughing and sneezing, which continued about half an hour, according to his own and wife's report, when he felt something give way within him. He heard a gurgling and the hernia had disappeared. In the morning he sent for Dr. Burke who found that the mass had gone. The ring was as large as a silver dollar. There was great pain and tenderness about the parts and he had local peritonitis. After a few days he recovered. He since has been fitted with a truss and the hernia has not come down. Dr. Burke concludes: "Would it not be well in some of these cases to give the patient a good pinch of hellebore to bring on sneezing? Perhaps it may tear away the adhesions and cause the gut to return. I would ask your readers if they ever met a case of hernia reduced in that manner."

THE BIOLOGICAL SOCIETY OF PARIS.

Stated Meeting, July 19, 1884.

M. Paul Bert, President, in the Chair.

(Special Report to The Medical Record.)

The scientific work of the meeting was begun by M. Rabuteau, who made a few remarks upon the

TANNATES IN THE TREATMENT OF CHOLERA.

He prophesied that the workmen in the tanneries near Bièvre would escape cholera in case of an epidemic occurring there. In the case of a patient attacked by diarrhœa in the first stage of cholera, he would begin by administering a laxative of castor-oil or the sulpho-carbolate of soda, and would follow this up by the wine or tincture of catechu or some other of the anti-cathartics containing tannin. He would permit the use of apricots, strawberries, or any fruits containing tannin, but would forbid melons.

M. Beauregard had been studying the

HABITS OF THE SPANISH FLY,

and related some of the facts which he had discovered in his investigations. The leaves of the lilac are the favorite food of these insects. The flies lay their eggs in the ground, digging a burrow some distance below the surface, and there depositing two little spheres each containing from sixty to eighty eggs. The grubs are hatched at the end of two weeks. Both the grubs and the flies subsist entirely on the saccharine juices of plants, and never eat the eggs of other insects. Cantharidine is present at every stage of development of the insect. Vesication may be obtained by using the eggs or the larvæ as well as by using the fully developed fly.

M. Rémy related some results which he had found to follow upon

EXCITATION OF THE SPERMATIC PLEXUS.

In the course of certain experiments upon the great sympathetic nerve in the Guinea-pig, he had found that irritation of a small ganglion, lying just anterior to the kidney, caused a seminal ejaculation, and when continued, excited an erection. The action was centrifugal, for, if the nerve were divided, central irritation produced no result.

M. Quinquand gave the results obtained by him in certain experiments made to determine

THE PATHOGENESIS OF URÆMIA.

The opinion of pathologists generally of the present day is that the uræmic symptoms are not caused by the accumulation of urea in the blood, but the speaker claimed that the experiments conducted by M. Gréhant and himself proved that this opinion was incorrect. In the frog, the subcutaneous injection of fifteen grains of urea was followed by convulsions, tetanus, and death from arrest of the respiratory movements. The heart continued to beat several minutes after the cessation of respiration. In the Guinea-pig, epileptiform convulsions and opisthotonus were produced. In the dog, the symptoms were those of coma, and were followed by death in from fifteen to thirty minutes. The dose of urea necessary to produce these results is rather large; in the Guinea-pig, 75 to 90 grains are required; in the rabbit, 120 to 150 grains; in a dog weighing 6½ to 9 pounds, 150 to 180 grains. The proportion of urea in the blood is, however, not large, only from three to six parts by weight per thousand.

M. Richet said that he had often injected many times larger amounts of urea in the dog without obtaining any results. He used the substance in very dilute solution.

M. Quinquand said that with dilute solutions there were never any uræmic symptoms, an increased secretion of urine was the only result produced.

M. Frank asked whether the so-called uræmic symptoms observed by M. Quinquand might not have been caused by the irritation of the skin, resulting from the

injection of these concentrated solutions, for M. Brown-Séquard had seen like symptoms produced by irritant injections.

M. Féré presented a communication upon

PARTIAL SOMNAMBULISM.

An hypnotized subject who is cataleptic or lethargic may, by means of friction made over the vertex, be thrown into a third somnambulistic state. If the friction be made over one side only the condition is one of hemi-somnambulism. If, instead of general friction over the vertex, strong pressure be made over certain portions of the scalp, partial somnambulism of that region, whose motor centre in the cortex corresponds to the point pressed upon, results. Thus one-half of the face, one arm, or one leg may be affected. It is even possible to cause partial somnambulism of the upper portion only of the face by pressing upon that part of the skull lying above a horizontal line prolonged from the level of the eyebrows, and behind a vertical line drawn posterior to the mastoid process. This was the situation of the cranial lesion in a case of traumatic tic of the eyelids observed once by M. Féré.

M. Gibier then related some experiments upon the

INOCULATION OF RABIES

in birds. He found that the intensity of the virus increased in direct ratio with the number of inoculations practised. The period of incubation, when the virus was injected into the anterior chamber of the eye, was twelve days.

The Society then adjourned.

Correspondence.

INTERNATIONAL MEDICAL CONGRESS.

(From our Special Correspondent.)

COPENHAGEN, DENMARK, August 16, 1884.

THE SUCCESS OF THE CONGRESS—THE NOTABLES PRESENT—THE SPEECHES OF JACOBI AND NOYES—AMERICAN ELOQUENCE — DR. SAYRE AND HIS PLASTER JACKET—HOW CRUDELI TREATED MALARIA—VIRCHOW AND HIS SUBJECT—PASTEUR AND HIS IMPRESSED AUDIENCE—THE COLLECTIVE INVESTIGATION COMMITTEE—SOCIAL ENJOYMENTS—WORK AND PLAY.

You have doubtless received by this time my full cable despatches of the meeting of the International Medical Congress here, and have formed an estimate of what has been done—not only what has been done in a strictly scientific but a social way. The meeting was a great success in every particular. The weather was charmingly pleasant, and all the other accesssories were at hand to enable the Committee of Arrangements to follow out their plan within as well as without doors to the satisfaction of every one.

Among the prominent medical men from New York who were present and took a more or less active part in the proceedings were Drs. A. Jacobi, H. D. Noyes, Joseph W. Howe, and Lewis A. Sayre. Dr. Jacobi made an impressive and telling address on the eve of the adjournment, and well represented the cosmopolitan spirit of the medical profession of America. Dr. Noyes also made a thrilling speech at the dinner of the Ophthalmological Section on Monday, in response to the health of the American visitors. He was merely a delegate of a large working community on "the other side" who had a deep sense of love and reverence for the old countries, and especially for Denmark, and he made his audience feel it.

Dr. Sayre gave some exhibitions of his plaster-of-Paris jacket, which being novel to most of his hearers attracted a good deal of attention. If any one who has attended the recent meetings of the British Medical Association for the past few years, or other medical gatherings in Great Britain and elsewhere, is not now acquainted with the Sayre jacket, the reasons why it should be used in all cases, and the way it should be used, he deserves to be pitied as an ignoramus, or at least an inattentive listener. Certainly the distinguished surgeon and his son have spared no pains to such an end, either as to time, place, circumstance, or surroundings. But, as before remarked, his demonstrations were well received. The most interesting subject presented in the addresses was that on malaria by Professor Crudeli, of Rome. This has doubtless been published with the cable despatches. The subject was one that interested practitioners generally, although some of the views enunciated by the distinguished hygienist were somewhat striking, if not heretical in their tendency. The courteous attention of the large audience throughout the delivery of the address attested its merit and its widespread applicability to the wants of his hearers.

Virchow drew a crowd of hearers, more on account of himself than his subject. He did his best to infuse interest into his theme, and this, considering his impressive delivery and forcible eloquence, is saying a great deal. But he was compelled for the most part to confine himself to abstruse reasoning on mere theories, and was at times tiresome and heavy.

Pasteur came before his hearers with the *éclat* of a star actor in a celebrated part. Both he and his subject were interesting, but the former even more than the latter. The audience hall was crowded to its uttermost, and there was infused in his delivery, in his presentation of striking facts, and in the apparently modest summing up of results, a sentimentality which told strongly on his hearers. But Pasteur is a great man, an original thinker, a hard worker, and one who knows how to make his work appreciated. The principal points in his address were cabled as fully as possible in the rush to get everything in the shortest time, but perhaps a little more of details as to experiments performed and their results may be acceptable just here.

When he had discovered his method of vaccinating dogs with hydrophobic virus, and so made many dogs insusceptible to hydrophobia, he requested from the government a competent committee to judge of his results. The request was granted by the Minister of Education (M. Fallières), who appointed Béclard, Paul Bert, Boully, Tisserand, Villemain, and Vulpian, members of the committee. He stated that the committee had just sent its report to the Minister. The following were its most important points :

Pasteur gave 23 vaccinated dogs to the committee. These were compared with 19 non-vaccinated dogs selected by the committee.

On June 1st 2 vaccinated and 2 non-vaccinated dogs were inoculated by trepanation from a rabid dog.

On June 3d 1 vaccinated and 1 non-vaccinated dog were bitten by a rabid dog.

On June 4th 1 vaccinated and 1 non-vaccinated dog were bitten by a rabid dog.

On June 6th the rabid dog died, and virus was taken from it and by trepanation inoculated into 3 vaccinated and 3 non-vaccinated dogs.

On June 10th 1 vaccinated and 1 non-vaccinated dog were bitten by another rabid dog.

On June 17th 1 vaccinated and 1 non-vaccinated dog were bitten by one of the non-vaccinated dogs, which had become rabid after the inoculation by trepanation on June 1st.

On June 20th 6 vaccinated and 4 non-vaccinated dogs were inoculated by injection into a vein.

On June 28th 2 vaccinated and 2 non-vaccinated dogs were bitten by a rabid dog.

The commission reported that of the 19 non-vaccinated dogs 3 out of 6 bitten became rabid, 5 out of 7 inoculated into a vein became rabid, and all the 5 inoculated by trepanation became rabid, but among the

23 vaccinated dogs not one single case of hydrophobia occurred.

One of the vaccinated dogs died on July 13th from *diarrhée noire*. At once some virus was taken from this dog and inoculated by trepaning into three rabbits and one Indian pig. All these four animals are still quite well, which is a certain proof that the dog did not die from hydrophobia. The commission, of its own accord, now intend to vaccinate twenty dogs in order to ascertain results independently of M. Pasteur.

Professor Pasteur finished his address by stating that animals are proportionately less infected by bites from dogs than by inoculation. He emphasized that his experiments had only produced results concerning animals, but that he considered it most likely that if the dog could thus be made insusceptible of hydrophobia, the source of this terrible disease in man would be extirpated, and the question as to prophylaxis both for dog and man would be solved.

Sir Wm. Gull's address on the importance of a collective investigation was well received although it dealt largely with truisms that were well appreciated by all progressive men. The adoption of the recommendation for a National Investigation Committee was a foregone conclusion. The selection was made from the different countries as follows, and at the next meeting of the Congress in Washington, there will probably be formulated some acceptable working plan. The representatives for the different countries were: For America—Drs. Jacobi, Austin Flint, and Billings; England—Sir James Paget, Acklan, Gull, Risdon Bennett, Mahomed, and Isambord Owen; for Germany—Ewald and Guttman; Norway—Bull; Denmark—Finè and Panum; France—Verneuil, and Lepine.

It was surprising to note the busy character of the members in attendance at the different general meetings and at the sessions of the sections. The attendance in all was large, and yet each listener was interested, and all this despite the thousand and one allurements from the municipal authorities and citizens generally for purely social enjoyments. But there was time left for these. The Tivoli Gardens was the great centre of attraction. There was dancing, concerts, and other varieties of light amusement, and thither the majority of the socially inclined repaired after the hard work of the day and evening. During the Congress a public luncheon was provided free of expense to the members, while public dinners were given every day by invitations. All the museums and hospitals were also thrown open to the members.

In my first cable I alluded to a slight confusion in the programme, but this was only manifest during the first day, as afterward the affairs of the Congress progressed like clockwork, with nothing in the way of unpleasant discussion or obstructive jar to mar the interest and harmony of the notable eighth session of the International Congress.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DULL SEASON—BRITISH VERSUS CONTINENTAL SPAS—THEIR LOSS OUR GAIN—CHOLERA—QUARANTINE HORRORS—CUSTOM-HOUSE TROUBLES—DEATH OF SIR ERASTUS WILSON.

London, August 16, 1884.

There is not much stirring just now in medical London. The medical schools are closed till October. Most of the societies closed some months ago. All the doctors who can have followed the example of their patients and rushed off either to the mountains, the moors, the country, or the seaside. Our British health resorts are more than usually crowded this year, owing to the presence of cholera on the continent. Many people who have hitherto paid regular visits to some of the continental spas every summer have been obliged to try and find a substitute this year in some of our own watering-places. The present season therefore promises to be a very profitable one to the inhabitants of our health and holiday resorts—most of them are crowded. At many seaside places bathing begins at four A.M. and goes on actively until the afternoon; at some, bathers may be observed literally "from early morn till dewy eve." Undoubtedly many even of those professedly in search of health are not invalids in any sense of the word; but a certain proportion of them are, and a good many fees are thus likely to drop into the pockets of our own medical men that would otherwise find their way into those of our foreign brethren.

The loss to the Continental spas is very serious. Some rough estimate may be formed of it from the diminution in the number of circular notes issued this year. One bank alone estimates that up to now it has issued three thousand notes less than the average of former years. Multiply this by the average amount represented by each note, and again by the number of banks issuing notes, and the total will be a good round sum.

The cholera is not the only deterrent to foreign travel. The fear of quarantine and its discomforts is a greater one even. Those who have had to submit to it are not slow to publish their sufferings in the daily newspapers as a warning to others. Foreign travel has enough discomforts already without this added. The custom-house officers are not usually remembered with kindly feelings by British travellers. Some years ago a relative of the writer's, who was travelling in Italy in medical charge of an English family, had an annoying experience. He carried with him a small medicine-chest. On the frontier the diligence stopped as usual, and the passengers all alighted to have their baggage examined. The medicine-chest was seized. In vain its owner protested it only contained medicines. The officials were inexorable. Finally he asked them to taste the medicines that they might be convinced of their nature. The invitation was not accepted, and the medicines were, after a long parley in the dusty road, finally allowed to pass. Their owner afterward learnt that what he ought to have done was to have given the custom-house officer a "tip" and then he would have had no trouble.

Sir Erasmus Wilson died last week at his residence in Kent. He was born in 1809, and became a member of the College of Surgeons in 1831, and a Fellow in 1843. He originally resolved to be a general surgeon, and became Assistant-Surgeon to St. Bartholomew's Hospital. He was the author of the well-known "Anatomist's Vade-Mecum," which has passed through nearly a dozen editions, the last of which was issued only a few years since. Twenty years ago it was perhaps the most popular anatomical text-book extant, and has sold well down to the present time. Not meeting with a success equal to his wishes in the field of pure surgery, Sir Erasmus (then simply Mr.) Wilson was advised to take up the skin as a specialty. This he did with the determination to succeed. His success was such that his name has become a household word, and his practice literally became enormous. Although married, he had no family, and he gave away a large portion of his earnings. He endowed a chair of pathology in the College of Surgeons (to which he was elected as the first professor), and another quite recently in the University of Aberdeen. The new wing of the Margate Sea Bathing Infirmary was built with a donation presented by Mr. Wilson. His gifts to various charities would take some time to enumerate. I need scarcely remind your readers that he brought Cleopatra's Needle to England, an exploit which cost him ten thousand pounds.

Mr. Wilson never held any skin appointment (except for a short time the purely honorary one of Consulting Surgeon to the St. John's Hospital for Skin Diseases), so his experience was drawn from private practice, but as this was so large he did not feel the want of a hospital clinic. "I see specimens of most varieties of skin dis-

ease *here*," he once remarked to a medical friend, looking round his spacious consulting room. He lived and practised for many years next door to the late Sir Thomas Watson. He was President of the College of Surgeons in 1881, and he received the honor of knighthood in the same year. He lived virtually retired during the last two years of his life at his house at Westgate. He was the author of numerous works on dermatology.

THE MORPHOLOGICAL STATUS OF THE CEREBELLUM.

To the Editor of The Medical Record.

SIR: Permit me to ask your readers not to interpret my silence respecting Dr. Spitzka's letter under the above title (The Medical Record, July 26, 1884) as indicating either that I have abandoned the view attributed to me, or that I am unaffected by the objections so ably advanced by that distinguished anatomist.

I say *the view attributed to me*, because Dr. Spitzka does not refer to the fact that in my discussions of the segmental constitution of the brain (*Science*, March 19, 1881, p. 135; "The Brain of the Cat," "Proceedings Am. Phil. Soc.," August 15, 1881; *Anatomical Technology*, November, 1882, pp. 405, 479, 482; "Cartwright Lectures," several places in Lecture I.) I have *provisionally* followed Von Baer and others in recognizing the existence of two encephalic segments caudad of the "optic lobes."

The matter will be more fully considered in the last part of the third "Cartwright," and forms the subject of a paper entitled "Do the Cerebellum and the Oblongata represent One Encephalic Segment or Two?" for presentation at the coming meeting of the American Association for the Advancement of Science, in Philadelphia. If Dr. Spitzka could attend the meeting, it would not only gratify me but further the solution of a difficult problem. BURT G. WILDER, M.D.

AN UNNOTICED FEATURE OF THE GROSS ANATOMY OF THE FOURTH VENTRICLE.

To the Editor of The Medical Record.

SIR: Observers of cerebral anatomy are familiar with the fine longitudinal striations which appear to pass from the anterior half of the fourth ventricle to the aqueduct, toward which they converge. It is not determined whether they are the result of shrinkage, through the action of hardening fluids; they seem to be most pronounced in those parts of the ventricular parietes where large cavities undergo a sudden contraction in passing into smaller channels, such as the infundibulum and the locality above mentioned. Bergmann gave a special name to those in the latter situation, terming them *Psalterium* and *Organon pneumaticum*. In no treatise, ancient or modern, do I find a very distinct appearance, which I have frequently noted, described. In the lateral angles of the fourth ventricle of a child aged fourteen months I found on either side three button-like elevations, into which the striæ described by Bergmann were continued, just as the stick of a drumstick joins its button-like termination. In another child their existence in the fresh (unhardened) brain was determined. They are paler than the rest of the ventricular flow in chromic acid preparations.

At first I supposed that these elevations were infantile features in the human brain, like the *crista fornicis* of Wilder, which, so far as I am aware, has been identified by that observer only in a child. On examining the fourth ventricle of the negro Jefferson, recently executed in Brooklyn, I found these "hordea," as I propose to designate them, very distinctly marked. On the right side there were two of these prominences, globular, separated by a narrow fissure, the aggregate dimensions being, antero-posteriorly, a little over one-eighth of an inch, each measuring transversely a sixteenth. On the left side there was a single eminence apparently equivalent to a fusion of two such as those on the other side; it resembled a long oval hill, running antero-posteriorly, with its anterior end making a deflection inward. In the several brains in which I have identified these bodies they were all situated directly laterad of the *forea*. In the negro, most of the striæ of the *psalterium* passed laterad of them, along the rising ventricular side-wall to pass into the roof of the ventricle. A few, however, passed toward the hordea, but without as distinctly connecting with them as in the infantile brains. In one of the latter, the three beautifully distinct hordea (resembling, as their name indicates, so many barleycorns) of each side had each a string of the psalter running into them, so as to resemble (as above indicated) three thick-headed drumsticks lying side by side. In several hardened specimens of the adult brain-isthmus I find these bodies to be as distinct as in the negro cited, alcohol specimens, as a rule, showing them less distinctly than such as had been first preserved in acid, chromic salts, or glycerine mixtures.

What the significance of these bodies is, whether they be mere thickenings of the endyma or not, I am unable at present to say. I have identified faint indications of these bodies in the corresponding situation in the sea-lion and found them absent in one monkey (cercopithecus), but not having examined the entire collection with reference to this point, am unable to say anything as to the general absence or presence of the hordea in the animal scale.

I may remark in conclusion, that the general physiognomy—if I may so term it—of the fourth ventricle in the negro referred to, was more infantile than that of any other human brain I have examined. The floor of this cavity in the child is marked by the deep depression of the so-called "fasciculus teres" elevation, the outer borders of the distinct grooves on the outer side rising up very steep. In the adult, ordinarily, the floor becomes generally flatter. The general development of this negro's brain was good. E. C. SPITZKA, M.D.

ENDORSED DIPLOMAS OF THE UNITED STATES MEDICAL COLLEGE.

To the Editor of The Medical Record.

SIR: Inasmuch as numerous inquiries have been addressed to the Board of Censors of the County Society in regard to the endorsement of diplomas by the United States Medical College, we have been advised to answer the following recent inquiries through The Record:

1. Is the Eclectic Medical College of Cincinnati, O., a reputable institution?

2. Is a diploma, issued by the above, and endorsed by R. A. Gunn, legal qualification for the practice of medicine?

If the writer refers to the Eclectic Medical *Institute* of Cincinnati, it is a reputable school and the diplomas are recognized by the Illinois State Board of Health, provided the graduate presents a written statement from the dean that he has studied medicine three years, and taken two full courses of twenty weeks each, extending over a period of sixteen months. The natural inference from this condition is that diplomas have been issued from said college to persons who have not met these requirements, but that the present management is entitled to confidence. The Court of Appeals has declared that the United States Medical College was illegally incorporated, and such disability never having been removed by subsequent legislation, every diploma issued, and every endorsement by R. A. Gunn as dean became null and void. As a measure of relief to the innocent victims of this now defunct institution, the Legislature last winter passed an act legalizing the diplomas issued by the United States College *prior* to the beginning of proceedings against it, April 21, 1883, provided the holders of said

diplomas had attended the required courses of lectures, passed a satisfactory examination, and been regularly graduated, in other words had not secured a diploma by the disreputable means believed to have been practised in some instances.

Very respectfully,

DANIEL LEWIS, M.D.,
Chairman of Board of Censors.

ELECTROLYSIS IN STRICTURE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Allow me a few words in reply to a criticism in the last RECORD of my article on the above subject by Dr. Meier. I do not propose to enter into any controversy upon this subject, and this will close the discussion on my part For it is apparent from the doctor's attempted contradiction of my position, that, in the words of a distinguished surgeon, "it is useless to argue with men who persist in making statements in direct opposition to those who are known to have the largest opportunities for scientific investigation and experience."

I claimed that it is impossible to cure organic stricture by the method of which we have heard considerable in the last few years, namely, the application of electric currents so weak as to be scarcely felt. That it was not to be expected from our knowledge of the laws of electro-therapeutics, and was not endorsed by the standard authorities. My "arbitrary dictum," as the doctor terms it, is based upon nearly twenty years' experience in the study and treatment of strictures and in the use of electricity. Any one can read the authorities for themselves. Sir Henry Thompson, Surgeon to University College Hospital, London, and Fessenden N. Otis, Professor of Genito-Urinary Diseases in the College of Physicians and Surgeons, and Surgeon to Charity Hospital, New York, authors of the most classical works upon stricture which have ever been written, and who have probably had the largest experience in this line of any men who ever lived, totally ignore electrolysis. "Althaus," the great English authority on electricity, and "Beard and Rockwell," the American, speak in very guarded and not favorable terms of the remedy. And so one might go through nearly the whole list of standard writers, college professors, and hospital surgeons who have had the greatest opportunities for studying and experimenting. Their ability or honesty cannot be questioned; their position certifies to the one, and their character, writings, and the absence of biasing motives to the other. The doctor claims that analogous conditions in other parts are cured in this way. The above remarks apply equally to this statement also. S. W. Gross, Professor of Surgery in the Jefferson Medical College, Philadelphia, in a recent elaborate article in the *American Journal of the Medical Sciences* on the "Treatment of Stricture of the Œsophagus," does not even mention electricity. And yet my critic has the assurance to deny all this and claim that the writer, and if him then all who agree with him, which embraces the great mass of the profession, are not sufficiently skilful to follow the directions laid down by the advocates of this method. But that the method itself is all right is not proven because a certain doctor does succeed with it anyhow, no matter whether any one else does or not.

In support of his statements he quotes a few of the reports of the remarkable effects of electricity which have appeared in the journals. All have heard this same kind of argument before, can weigh the evidence of both sides, make the "experimentum crucis" for themselves, and draw their own conclusions. My experience with dilatation, divulsion, electrolysis, and dilating urethrotomy, leads me to believe that very few cases of stricture are permanently cured, except by tearing (divulsion) or cutting; and the former process has generally been abandoned as having no advantages and some disadvantages compared with the cutting operation. Nearly every stricture of the straight urethra should be, and can be cured permanently by cutting. An external constricting band or a contracted meatus is cut unhesitatingly. By putting the urethra on the stretch by the urethrotome an internal one is cut with nearly equal facility with little or no pain and with almost perfect safety. "Operations confined to the straight urethra are *as a rule* never followed by constitutional disturbance," but no instruments should be passed into the bladder at the same time, for the passage of a sound not unfrequently causes chills and other constitutional effects. The rationale of cure is by relieving spasm and congestion, which must exist more or less about every stricture, to promote a healthy circulation and absorption of the deposit. Over 1,100 cases without a death, and with only a very few cases of urethral fever, serious hemorrhage, or inflammation, and these few in operations on the deep urethra, are reported in Otis' work. It is not until we pass around the pubic curve that trouble usually begins. Fortunately the great majority of cases are in the straight urethra, slight contractions of which the only symptom is gleet, with more or less spasmodic contractions deeper. "These cases are of daily occurrence and often pass unrecognized, the gleet being treated, the stricture overlooked. Too much stress cannot be laid upon the importance of exploring the urethra in every such case, and if the slightest obstruction is found, removing it."

H. W. STREETER, M.D.
104 WEST MAIN STREET, ROCHESTER, N. Y.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 17 to August 23, 1884.

CRAMPTON, LOUIS W., Captain and Assistant Surgeon. To report at Creedmoor (L. I.), N. Y., not later than August 30th, as competitor; and in addition thereto, as medical officer of the detachment of competitors. S. O. 41, Division of the Atlantic, August 20, 1884.

COCHRAN, J. J., First Lieutenant and Assistant Surgeon. Assigned to duty at the Presidio of San Francisco, Cal. S. O. 81, Division of the Pacific, August 16, 1884.

BIRMINGHAM, H. P., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence. S. O. 162, Department of the Missouri, August 12, 1884.

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Walla Walla, Wash. Terr., and to take station at Vancouver Barracks, Wash. Terr. S. O. 120, Department of the Columbia, August 13, 1884.

FISHER, W. W. R., First Lieutenant and Assistant Surgeon. When relieved by Assistant Surgeon Cochran, to report in person to Commanding General, Department of Arizona, for assignment to duty in that department. S. O. 81, C. S., Division of the Pacific.

WOODWARD, J. J., Major and Surgeon. Died, August 17, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending August 23, 1884.

RIXEY, P. M., Passed Assistant Surgeon. Orders to U. S. S. Lancaster revoked. To continue on special duty.

MARTIN, C., Medical Director. To be retired August 21, 1884.

HEYL, T. C., Surgeon. Detached from U. S. S. Independence, ordered to U. S. S. Adams.

AYERS, J. G., Surgeon. Detached from U. S. S. Adams, placed on waiting orders.

CURTIS, L. W., Assistant Surgeon. Detached from U. S. S. Adams, placed on waiting orders.

STEPHENSON, F. B., Passed Assistant Surgeon. Detached from Navy Yard, New York, ordered to C. S. S. Bache.

DERR, E. Z., Passed Assistant Surgeon. Detached from C. S. S. Bache, placed on waiting orders.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 23, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
August 16, 1884	2	30	34	2	52	24	0	0
August 23, 1884	0	26	32	1	50	22	0	0
Deaths.								
August 16, 1884	0	3	2	2	7	12	0	0
August 23, 1884	1	16	5	1	10	11	0	0

THE VAGARIES OF A NEEDLE.—Under the above head Dr. John Burke, of this city, writes: "Miss A——, seventeen years of age, came to my office last October suffering from an abscess behind her right ear, over mastoid process. She had this trouble for four years, and for ten years she had a discharge from her ear, sometimes fetid and sometimes not. She was also partially deaf in that ear. Her mother had tried many ear surgeons, but the discharge from the ear and the deafness continued. Now, the abscess had two openings, one above and the other directly below, about one inch apart. Under ether I laid open the parts to the bone. There was no necrosis. Next day a poultice of flax-seed meal was applied. In three days a common sewing-needle came out of the wound, not much rusted. History: Ten years ago the child, being seven years of age, was playing with a needle in her mouth; it was swallowed. It caused some strangulation. It could not be found by the doctors who examined the throat. About four months afterward the child was taken with pain in the ear and otorrhœa, which, notwithstanding good surgical treatment, continued for ten years. For four years she suffered with an abscess over mastoid process, sometimes healing, and then suddenly breaking out. On March 1st the needle came out. Since then the abscess has healed, the discharge from the ear has ceased, and the patient can hear very fairly in the ear, but not as well as in the other side. But all pain and tenderness has gone."

OVARIOTOMY IN THE CORPULENT; OVARIAN CYST IN A WOMAN AGED NINETY.—Dr. W. P. Giddings, of Gardiner, Me., sends us the following instructive histories: "On June 26, 1882, I removed from Mrs. S——, twenty-six years of age, an ovarian multilocular cyst, weighing with its contents fifty pounds. She had been tapped four times, the last two by myself, removing respectively 33 and 35 pounds. The abdomen was excessively pendulous, and after closing the wound there was a very deep sulcus into which I judge a pint of fluid might have been poured and retained. Desiring to avoid the retention and burrowing of pus about the wound, I placed adhesive strips to within half an inch of the wound and drew them around toward the spine, then crossed the wound with adhesive straps supporting it in the usual way. I had the cicatrix thus supported for several months, reinforced by the bandage. Recovery was uninterrupted, and there was gradual retraction of skin and muscles to a normal state. On June 16th of the present year, I delivered the lady of a fine healthy boy of 10 pounds weight, and found the cicatrix of wound had not yielded in the slightest degree, and during labor there seemed to be as much force exercised by the muscles as is usual. Convalescence rapid and complete. Case 2: Mrs. A——, ninety years of age, had for eighteen months noticed a gradual enlargement of abdomen, and for some few months œdema of feet and limbs, which had greatly increased, rendering locomotion impossible, and confining her to bed. To add to her discomfort, profuse salivation had come on, preventing her taking food or getting sleep. General dropsy had been diagnosed, and I was called in consultation. There had been at times during the past few months quite a "show." I instituted a careful examination and diagnosed ovarian cyst of left side with thin fluid. The case was frankly stated and tapping advised, her extreme age forbidding the thought of a radical operation. The old lady, unusually intelligent, with faculties remarkably well preserved, submitted at once to the operation, remarking during it, "Doctor, I enjoy seeing that fluid run; surgery has advanced since I was a girl." This was done April 10, 1884. At present writing she is well and hearty, though the cyst is gradually filling. Who has seen so old a person develop an ovarian tumor?"

A NEW, SUCCESSFUL, AND PALATABLE MEDICINE FOR THE TREATMENT OF TAPE-WORM.—Under the above title Dr. Howard Pinkney, writing from Sharon Springs, describes his experience with the oil of the pine needle, made from the *pinus punilio*. A hall-boy of the hotel had suffered for five years from tape-worm. He had been treated for four years in New York, but never had succeeded in getting rid of over four feet of links at a time. Dr. Pinkney not being able to get any male fern, pelletierine, or pumpkin seeds, therefore tried the following experiment: "The patient fasted from breakfast, and at nine P.M. he was given one teaspoonful of oil of the pine needle in half a glass of milk. The following morning, as there was no perceptible action of the medicine, the dose was doubled. This, the boy said, had a most agreeable taste. One hour later he took a dose of castor oil, and in the course of two hours after this he passed an entire tænia solium measuring fifteen feet six inches in length and one-half inch at its broadest part, gradually tapering down to almost a thread. To be positive that none remained behind, he was given two teaspoonfuls more, but no sign of any worm or part thereof passed. This oil," writes Dr. Pinkney, "contains no turpentine, is fragrant in its odor, and when mixed with milk very agreeable to the taste. It produces no strangury, tenesmus, or other unpleasant or distressing symptoms. The patient can generally pursue his ordinary avocation." Our correspondent would be pleased to know if any of our readers have ever read or known of its use in similar cases.

THE CHOLERA GERM AND ITS DESTRUCTION.—Dr. Koch has found large numbers of different kinds of germs in the intestines and discharges of cholera patients, and among them one almost new kind which seems peculiar to cholera. This form, which was not round, or dot-like, nor rod-shaped, had been previously noticed and described by Dr. Bristowe, of England, a well known medical author, as early as 1867. Other more common forms of germs were found in the dejecta and intestines by Bohm as early as 1838. Round or dot-like bodies were detected by Brittain and Swayne in Bristol, England, in 1849, and confirmed by Hugh Bennett, of Edinburgh. Pouchet, Davaine, and Paccini saw them again in 1854 and 1856. Dundas Thompson and Dr. Hassell, quoted in the United States Cholera Report for 1873, also wrote about them in 1854, and stated that they thrived most in warm alkaline fluids, when contaminated with organic matter in a state of decomposition. The rice-water discharges of cholera were found to be alkaline and very prone to putrefaction, and acids were first suggested as germicides and as curative remedies for cholera. In

1866 Dr. MacNamara, one of the very best writers on cholera, noticed the same things and was inclined to believe that the cholera germs died naturally in about three days. In 1872, Nedwetsky, also quoted in the United States Cholera Report for 1873, p. 32, gave us still more positive information. He put ten grains of quinine in two teaspoonfuls of rice-water discharges which were swarming with germs, and they were not only alive on the second and third days, but by the fifth day large masses, or new colonies of them, had formed. He then put thirty grains of camphor in two teaspoonfuls of rice-water cholera discharges and found that the germs lived and thrived. Next he put five drops of strong carbolic acid in two teaspoonfuls of rice-water discharges, but the germs remained alive and active. On the fifth day he added five drops more of carbolic acid but did not kill the germs. Then he put first one teaspoonful and then two teaspoonfuls of tar in two teaspoonfuls of rice-water discharges, but the germs continued to live, move and thrive. Then he put ten grains of calomel in two teaspoonfuls of rice-water discharges, but the germs continued to live and move among the particles of calomel which had settled at the bottom of the glass; and by the fifth or sixth day great numbers and masses of new germs had formed. Then he put one teaspoonful of laudanum in two teaspoonfuls of rice-water discharges, but the germs were alive on the second and third days, and on the sixth day only a few of them were benumbed. Next he put one teaspoonful of tincture of nux vomica in two teaspoonfuls of rice-water discharges, but most of the germs lived up to the tenth day, and then only a portion of them were dead and motionless. One teaspoonful of chloral was put in two teaspoonfuls of rice-water discharges, but the germs were not killed.

If there is any value in such careful and ingenious experiments they seem to prove that all these powerful remedies are useless in cholera. Nedwetsky was inclined to believe that they might be useful in cholera morbus and other allied diseases, and as one-half of the cases of real cholera recover, that they had obtained a fictitious reputation. He was destined to be more successful with other remedies. He put ten grains only of tannin or tannic acid in two teaspoonfuls of rice-water discharges, and in two hours an innumerable number of germs were found without life or motion. None of them came to life again up to the tenth day, even after they were put in distilled water to revive them. Dilute sulphuric and nitric acids, made by putting twenty drops of the strong acids in an ounce of water, and adding two teaspoonfuls of this to two teaspoonfuls of rice-water discharges, killed the germs at once. Very dilute muriatic acid, made by putting three drops only of the strong acid in six ounces, or nearly half a pint of water, killed the majority of the germs. Chlorine water killed the germs at once. Sulphate of iron in concentrated solution also killed the germs, and chloroform also. It is now claimed that all these germs were merely common germs or bacteria such as cause ordinary putrefaction. But all the rice-water discharges were taken from well-marked cholera cases which had been attended by Nedwetsky and the others during life and examined after death. We have apparently gained fixed points in the treatment of Asiatic cholera, which some are not willing to surrender. Healthy acid gastric juice will destroy the germs of cholera, and if sufficient of it be present in the stomach, rice-water cholera discharges may be, or at least have been, swallowed with impunity. In a jail in India some experiments were being carried on; rice-water discharges were put in a very large glass of water; nineteen convicts accidentally drank of this; in consequence four or five weak and dyspeptic patients died of cholera and the rest all escaped without a sign of disease. Muriatic acid is the base of the acidity of the gastric juice, and common table salt is a muriate of soda or a combination of muriatic acid and soda. Sulphuric acid has a well-established reputation in the treatment of cholera. Koch has added alum, which is a sulphate of alumina that kills his germs in a one per cent. solution. There is no harm in adding a little sulphate of morphine to these remedies, for opium has much palliative, if not curative, influence over cholera. Sulphate of copper is suggested by Koch, who says it will kill his germs in the very dilute solution of one part to 2,500 of water. And corrosive sublimate in the proportion of one to 20,000. But the great difficulty in the treatment of cholera lies in the fact that huge quantities of alkaline fluids are poured out into the stomach and bowels; these have to be measured by quarts or gallons rather than by pints or ounces, and all has not only to be neutralized but rendered acid before the germicides will act. If it takes ten drops of dilute sulphuric acid to kill the germs in two teaspoonfuls of rice-water discharges, how much will it require to deal with quarts at least: it would seem that rather large doses frequently repeated are required; and we can judge of the frequency of the repetition of the doses by the use of litmus paper to the discharges; when these become acid the doses may be lessened. And now would also be the time to try the more powerful remedies, viz., sulphate of copper and corrosive sublimate, if any one wishes to do it; they will be inoperative, though alkaline fluids. Lemon juice and vinegar have always been forbidden in cholera, but acetic acid, the basis of vinegar, is an efficient remedy.

Rectal Etherization.—Dr. O. Wanscher writes in the Copenhagen *Hospitals-Tidende*, of May 28, 1884, giving an account of the history of rectal etherization and of the advantages and disadvantages of this method. He states that in 1847, immediately upon the introduction of anæsthesia for surgical operations, Pirogoff conceived the idea of administering ether for this purpose by the rectum. Magendie's experiments upon animals, however, demonstrated the danger of injecting fluid ether into the rectum, many of the animals so treated passing into a state of dangerous or even fatal collapse, and Pirogoff was therefore led to experiment with the vapor of ether passed into the bowels. The method was described by him in a pamphlet published in St. Petersburg in 1847, entitled "Recherches sur l'étherisation," and also by Ekstromer who recommended its employment instead of tobacco clysters in the treatment of incarcerated hernia. The latter used it also with success for the relief of renal colic. But upon the introduction of chloroform, Pirogoff, together with most of the European surgeons abandoned ether, and then rectal anæsthesia passed into oblivion. The method was revived again by Wanscher, who published an article on the subject in the *Hospitals-Tidende* in 1882. The apparatus used by him, which is nearly identical with that of Pirogoff, consists of a bottle to which is attached a flexible tube about two yards in length, and provided at the other extremity with a nozzle with a stop-cock attachment. At the end near the nozzle the tube passes through a flask in which it is looped several times. The bottle is placed in a vessel of hot water, and the flask is also filled with hot water in order to prevent any condensation of the vaporized ether before it enters the rectum. By means of the stop-cock it is possible to administer or withhold the anæsthetic at pleasure, without withdrawing the tube. Dr. Wanscher has induced anæsthesia by this method successfully in a number of cases, especially in operations about the head and neck, and when openings were to be made into the thoracic cavity for the evacuation of the fluid in empyema.

A Genius to Fail.—Speaking of the causes of failure in life, Tourgee says: "Trying to carry too big a load. I don't know about a professional man's failing if he works, keeps sober, and sleeps at home. Lawyers, ministers, and doctors live on the sins of the people, and, of course, grow fat under reasonable exertion, unless competition is too great. It requires real genius to fail in either of these walks of life."

THE MEDICAL HISTORY OF THE CASES OF THE SURVIVORS OF THE LADY FRANKLIN BAY EXPEDITION.

By EDWARD H. GREEN, M.D.,

PASSED ASSISTANT SURGEON U.S.N.

As a preliminary to a medical history of the cases of the survivors of the Lady Franklin Bay Expedition, it is well to give a brief résumé of their mode of life at Camp Clay, their quarters, rations, etc., so as to better appreciate the condition in which they were found.

On September 29, 1883, Lieutenant Greely landed with his party at Baird Inlet after thirty days' exposure, drifting on an ice-floe; the record left at that time stated the *party was all well.* Having sent an advance detachment ahead, it was found and reported that a cache of provisions existed at Cape Sabine (fifteen miles further to the northward than he was at this time). It was deemed expedient to move the whole command up to that neighborhood rather than send for the provisions and winter at Baird Inlet. Finally, on October 25th, they moved around to a point between Cape Sabine and "Cocked Hat Island," lat. 78° 45′ N., long. 74° 15′ W. The site of their winter quarters was sheltered between high ridges of mountains, which screened them in a measure from the northerly and southerly winds. A glacier was situated at the foot of the mountain, on either side of them, about a mile distant. They constructed a house of loose rocks and moss, the walls being 3 feet in thickness. The roofing consisted of old canvas stretched over a boat. The dimensions of the house were 25 feet long by 17 feet wide by 4 feet high, making the cubic air space 1,700 feet. In this the twenty-five members of the party lived all winter, having a cubic air allowance of about seventy feet for each man. The whole party could barely squeeze in and lie at length, two or three being obliged to occupy the same sleeping-bag. The effects of this diminished air space will be seen later on. Their hut was but 100 yards removed from the ice-foot of the Sound, and 200 yards to the south of them was an artificial lake, from which they drew their water-supply by melting up ice. As the sea-water strained into this lake, they were drinking brackish water all the while.

On November 1st Lieutenant Greely took a careful account of his stock of provisions, and found there was but a whole ration for each man (estimated as an army ration, about forty-six ounces solid food per diem) for forty days. Dr. Pavy and he advised together, and it was with some reluctance that they determined to divide up the rations so as to make them last until March 1st, putting aside from time to time so that at the end they would still have ten days' supplies left with which to attempt the trip to Littleton Island, if the Straits were frozen over. Dr. Pavy did not think the party could exist on the ration during the winter; but the common voice was to make it go as far as it would, so each man was given the following daily allowance: Meat and blubber, 4.33 ounces; bread and dog-biscuit, 6.5 ounces; canned vegetables and rice, 1.40 ounce; butter and lard, 0.75 ounce; soup and beef extract, 0.90 ounce; berries, pickles, raisins, and milk, 1 ounce, making the daily allowance for the four months 14.88 ounces. During the winter the following amount of game was secured, which added to their stores: two seals, yielding about 120 pounds of meat; one bear, yielding 300 pounds of meat; eight foxes, 4 pounds each; and sixty dovekies (Uria brunnichii), a small bird weighing about a pound.

March 1st.—Found the party intact with the exception of Sergeant Cross, who died in January with well-marked scorbutic symptoms, the only case of pronounced scurvy that developed; and Hans, their Eskimo hunter, who was lost in his boat while hunting seals early in February. The Straits having been kept open during the winter by a succession of violent gales, the attempt to cross to Littleton Island had to be abandoned, and their ration was still further reduced to the following allowance: meat 6.8 ounces; bread and dog-biscuit 3.2 ounces, the rest of their stores being exhausted. The stores were divided up so as to last until May 12th. The sun had returned by this time, after an absence of one hundred and twenty-eight days, and those employed as hunters caught the sea-fleas or shrimp, a small crustacea ½ to ¼ in. long, consisting of about four-fifths shell and one-fifth meat. From 1 to 3 ounces of these a day—according to the catch—were allowed in addition to the ration. After the last reduction the party began to weaken and die off rapidly. About March 24th the whole party was overcome with asphyxia, and nearly lost their lives, owing to the atmosphere being surcharged with carbonic acid; they had lit their alcohol stove in the hut to cook a meal, without previously having removed the rags from the vent-hole in the roof. The remaining oxygen of the air was soon consumed by the stove, and the whole party were seized with faintness, vertigo, and dyspnœa. It was with the greatest difficulty they struggled from their sleeping-bags, and stumbled and were helped into the open air, many fainting away and dropping unconsciously after reaching the open. Being poorly clad for a temperature such as prevailed outside at the time (—46° F.), many were frostbitten. The after-effects of this mishap remained for a long time and weakened many of them. After May 12th everything like a regular ration was exhausted, and they struggled on as best they could, catching the shrimp (which they boiled) gathering reindeer moss, which when boiled yields a mucilage (similar to Iceland moss), and boiling up the seal-skin linings of their sleeping-bags (from which a gelatinous mass was extracted). It was not until they had exhausted the supply of moss around the camp that they gathered the black lichen (crêpe de la roche) growing on the rocks and boiled that. Dr. Pavy spoke strongly against its use, as he had the authority of Kane and Hayes that when eaten it would produce a diarrhœa, which, in their weakened condition, would be fatal. They had no fuel for artificial warmth, and barely sufficient to allow for melting the ice for procuring drinking-water, and to cook a meal every other day, so that the living temperature of the hut for the winter was from 5° to 10° F.

They recognized the fact that the nearest they could approach a state of hibernation the better were their chances of getting through. Only those employed as cooks and hunters exerted themselves much, and they were given a double ration. The rest of them occupied their sleeping-bags and slept sixteen to eighteen hours out of the twenty-four. In answer to complaints of hunger Dr. Pavy's motto was, "qui dort dine," which was philosophical without being filling.

There seemed to be but little acute suffering from the lack of food, it was only after the introduction of food into the stomach that the craving became great; for

days they went without food without actually suffering. The deaths seemed to take place finally from heart trouble (hydrops pericardii); the feet and face became œdematous; for a day or so they would complain of pains over the heart, have a spasm of pain over præcordia, a slight general convulsion, and all would be over. Their chief suffering during the winter was from constipation; many went eight to ten days without a stool, and one as long as sixteen days. The fæces became so hardened and impacted in the rectum that at each operation they were obliged to dig them out with their fingers, the abdominal muscles being too weak to extrude the mass; nearly every one would faint, after having a stool, of sheer exhaustion.

When it is considered that for nine months they were on the ration as detailed, had nothing but brackish water to drink, no artificial warmth, living in a temperature of five to ten degrees for the winter, with a cubic air space of seventy feet per man, the condition in which the survivors were found will not be wondered at. There were but seven out of the twenty-five found alive. These were A. W. Greely, first lieutenant, U.S.A.; Henry Beiderlick, hospital steward; D. L. Brainard, sergeant, U.S.A.; Thomas Connell, private, U.S.A.; Joseph Ellison, sergeant, U.S.A.; Julius Frederick, sergeant, U.S.A.; Francis Long, sergeant, U.S.A. The four first mentioned were taken on board the flagship Thetis and placed under my care, and with them this paper will principally be concerned.

On landing at the camp, the condition of the party was so desperate that a delay of two hours was necessary to restore them sufficiently to permit their being removed on stretchers to the boats and taken off to the ships. Thomas Connell, private, was in extremis, was pulseless, unconscious, and unable to swallow; limbs cold and respirations barely noticeable. Auscultating over the heart, the sounds were heard very indistinctly by propping him up; forcing open the jaws, a teaspoonful of brandy was slowly poured into the back of the throat. The effect of the stimulant was soon noticeable, as a faint pulse appeared at the wrist; in ten minutes he could make an effort to swallow, when more brandy was adminstered, followed by some warm condensed milk at intervals. The rest of the party were served with brandy, milk, and beef essence, and finally transported to the ships.

The time and space would hardly be allowed me to give more than a brief detail of the cases, and as they closely resembled each other, both in symptoms and treatment, I will confine myself to the case of Lieutenant A. W. Greely more particularly, alluding to anything peculiar in the other cases.

June 22d, 11 P.M.—A. W. Greely, lieutenant, U.S.A., aged forty. Disease asthenia; on admission fainted after being carried below in the ward-room and vomited; administered ammonia spts. aromat. 6 c.c., renewed in ten minutes; placed in the berth; given a teaspoonful of raw, fresh beef, minced; clothes were carefully cut off of him and heavy red flannels, previously warmed, substituted.

On examination his body emitted a sickly offensive odor (as of stale urine); emaciated to a degree. Skin hanging from limbs in flaps; face, hands, and scalp blackened with thick crust of soot and dirt (had not washed or changed clothing for ten months). Nervous system: excitable and irritable; at times almost irrational; eyes wild and staring; insists on talking, craving news, and demanding food; complains of no pain. Digestive system: tongue dry and cracked, heavy brownish-black coat; ravenously hungry; abdominal cavity hollow and lying almost in contact with vertebral column; no movement of bowels for six days; liver dulness; on percussion confined to right hypochondriac region. Respiratory system: respirations 12 per minute; auscultation and percussion reveal no abnormal condition of lungs; vesicular murmur puerile. Circulatory system: pulse 52, soft or compressible; auscultation shows marked murmur (blowing) in systole over base of heart. Integumentary system: skin cold and clammy, sickly odor emanating from it, shrivelled and sallow; temperature 97.2° (under tongue). Locomotor system: great muscular waste; unable to move or stand without support; body weight 120 pounds; weight before leaving Fort Conger in August, 1883, 168 pounds. Urinary system: no specimen obtainable. Treatment: From 11 P.M. till 8 A.M., alternated every half hour, teaspoonful of raw, fresh beef (minced) with teaspoonful of milk punch; enjoined strict quiet; pulse then rose to 60 per minute, soft; temperature 97°.

June 23d.—Nervous system: mind still active and restless, compelled to allow him some home letters to read, after which became more composed; has not closed his eyes; talks rationally, but shows loss of memory, as often repeats himself. Digestive system: had a small highly offensive stool; felt quite faint; afterward passed considerable wind from bowels; abdomen tympanitic; tongue still dry and coated. Circulatory system: pulse slightly stronger, 60 per minute; respiration 12 per minute. Integumentary system: same offensive odor; temperature, A.M., 97.8°; P.M., 98°. Locomotor system: still unable to rise up without help; muscles very soft and flabby; some stiffness and pain in the joints. Urinary system: urine passed in twenty-four hours, 1,630 c.c., specific gravity 1.014; acid, highly albuminous ($\frac{1}{10}$ tube). Treatment: Continue raw fresh beef at intervals of an hour, with a raw onion, finely cut up, added; also, milk punch, half an ounce every two hours; no medication.

June 24th.—No sleep; mind more tranquil, but too active; great desire to talk and read; less persistent in demanding food; complains of soreness in limbs; tongue presents a moister appearance; bowels slightly distended with gas; no stool; pulse, 62°, not so thready; heart sounds stronger; still a pronounced anæmic murmur. Blood examined microscopically shows large increase of white corpuscles; at first the field ($\frac{1}{10}$ objective) appeared filled with the nucleated corpuscles; close examination showed the proportion to be about one to twenty red; the red corpuscles show but little disposition to cohere and run into "rouleaux," and lacked the distinctive biconcave disk shape; edges full and round (not ragged). Urine passed in twenty-four hours, 1,660 c.c., highly albuminous; no casts revealed by microscope; skin clammy, dirty mottled yellow. Temperature, A.M., 97.6°; P.M., 98°; muscles sore; slight œdema of hands and ankles. Treatment: Sponging with tepid water, afterward briskly rubbed with flannels, and a little lin. sapo. Small quantity of oatmeal (thoroughly boiled), four ounces allowed in morning; beef essence, Liebig's, one drachm in hot water every four hours. Continue scraped beef and onion; no medication.

June 25th.—Marked improvement; mind more tranquil; talks quietly without excitement; slept two or three hours naturally, awoke refreshed. Tongue beginning to clean; had a large dark semi-solid stool; odor offensive in the extreme, evidently but little biliary secretion poured into alimentary canal. Pulse, 65°; some strength; respiration, 14°, principally costal; skin losing clammy feel; emanation still sour and offensive from it. Temperature, A.M., 98.2°; P.M., 98°; muscles sore, ankles puffed. Treatment: Shampooing muscles with dry cloths; no change in diet; no medication.

June 26th.—Allowed to sit up in bed and read a little; slept six hours soundly during the night; mind tranquil; has a loss of memory of words; tongue cleaning, still a heavy coat at the back; bowels moved twice; stools pitchy and offensive; abdomen tympanitic, considerable borborygmus; pulse, 65; heart sounds stronger; murmurs still pronounced; urine passed in twenty-four hours, 1,800 c.c.; specific gravity, 1016; albumen not decreased; no change in condition of skin. Temperature, A.M., 98°; P.M., 98.8°. Treatment: Sponging and friction. Same dietary with tr. ferri muriat., 5 c.c. t. i. d.

June 27th.—Still extremely weak; voice stronger; mind easier; amnesic aphasia marked; appetite still morbid, always hungry; considerable flatulency; no stool; aspect of skin somewhat improved in appearance; still dirty yellow (in spots). Temperature, A.M., 98.4°; P.M., 98.8°; pulse, 66; respiration, 14; urine albuminous (⅛ tube), 1,950 c.c. in twenty-four hours; specific gravity, 1.018; muscles beginning to fill out; very soft. Treatment: Dietary increased to eight ounces broiled steak in morning; continued ferri muriat.

June 28th.—Gaining strength; dressed and sat up for a couple of hours, then felt exhausted and returned to bed; mind quite tranquil; slept well; appetite still morbid; bowels moved; no change in character of stool; liver still inactive. Pulse, 66; fairly good tone. Anæmic murmur not so marked. Temperature, A.M., 98.2°; P.M., 98°. Urine passed in twenty-four hours, 1,860 c.c.; specific gravity, 1.018; albumen present. Treatment: Takes food at five stated intervals: 6 A.M., oatmeal, 4 ounces, broiled steak, 8 ounces; 10 A.M., Liebig's beef essence, 1 drachm in teacup of warm water; 2 P.M., one soft-boiled egg with milk toast; 6 P.M., raw minced beef and onion; 10 P.M., Liebig's essence of beef. Continue tr. ferri muriat., 6 c.c., t. i. d.

June 29th.—Dressed and assisted to walk in ward-room a few steps; muscles soft; very weak; limbs filling out; body weight, 129½ pounds (gain of 9½ pounds for the week). Pulse, 68. Urine, 1.650 c.c. in twenty-four hours; albumen less. Temperature, A.M. and P.M., normal. Bowels moved naturally; stool still pitchy and offensive. Treatment: Continue the same.

June 30th.—Sleeps naturally and awakes refreshed; allowed to read and talk; walks around for an hour or so with support; limbs filling out; feet œdematous toward night. Appetite still morbid, unable to be satisfied with his allowance; good movement of bowels; albumen disappearing; heart sounds stronger. Temperature normal. Continue restricted diet and iron.

July 1st.—Felt quite refreshed on awaking; had slept well during the night; enjoyed morning meal, and ate without asking for more. As the sun was shining brightly, was assisted on deck and sat in the air (well bundled up) for an hour. Had but little appetite for mid-day meal. At 4 P.M. a small, dark, offensive stool; strained considerably and was much exhausted afterward (nearly fainted); administered spts. frumenti, ℥ ss. in aqua. At 6 P.M. complained of severe pains in abdominal muscles and over the region of the liver (pains resembling hepatic colic); considerable febrile disturbance. Pulse, 98. Temperature, 100.2°. Administered quin. sulph., 3 c.c., at 8 P.M.

July 2d.—Feels much prostrated and weak; muscular pains and soreness over abdomen and back. Complexion sallow; appetite poor. Temperature, 8 A.M., 98.8°; 12 M., 99°; 4 P. M., 99.2°. Exhibited hydrarg. chlorid. nit., 3 c.c. at 8 A.M., repeated dose at 2 P. M. Bowels moved three times, last evacuation watery. Felt weak, but free of cramps; headache disappeared. Light diet of oatmeal and milk. Discontinued tr. ferri muriat.

July 3d.—Still weak; muscular soreness over abdomen; no sharp pains; two loose evacuations from bowels. Appetite returning. Pulse, 68. Temperature normal. Whiskey toddy, ℥ ss. t. i. d.

July 4th.—Considerable improvement; pains have disappeared from muscles, tongue cleaner, complexion better. Allowed to sit up to his meals. Urine much improved; albumen (⅛ tube); specific gravity 1.022. Resume tr. ferri muriat., also vin. Portense, ℥ j., t. i. d. before meals.

July 5th.—Gaining strength gradually; muscles soft; knees weak; encouraged to take some exercise daily, weather permitting, in the open air. Digestion good; appetite under better control; liver still torpid; regular movement of bowels; skin clearing, lost clamminess; sleeps well. Continue same. From this time forth gradual improvement. Blood again examined microscopically shows marked diminution of white corpuscles.

On July 8th, no albumen found in urine. On July 12th, anæmic murmur very indistinct. On July 17th arrived at St. Johns. Condition sufficiently improved to warrant his going ashore for exercise; muscles still weak and sore; filled out rapidly.

July 19th.—Had a slight attack of intestinal indigestion; was living ashore at the consul's and committed an error in diet; suffered for two days.

July 25th.—Allowed to eat three full meals daily, with certain articles restricted; encouraged to exercise in open air. On the trip from St. Johns to Portsmouth, N. H. (July 26th to August 1st), ran into damp, moist weather; felt much prostrated, and muscles ached. Given quin. sulph., 18 c.c., every night during the run. On being transferred at Portsmouth, his body weight was 169 pounds, representing a gain of 49 pounds in six weeks—9½ pounds first week, 15 pounds second week, 8 pounds third week, 7 pounds fourth week, 5½ pounds fifth week, 4 pounds sixth week.

Remarks.—Vital depression, as exhibited by the temperature, not marked; digestion fairly good all the time; nervous system soon calmed. Microscopic examination of blood disappointing; exhibiting no unhealthy character of red blood-globules. Albumen disappearing. Anæmic murmur disappearing, showing it to be simply due to hydræmic condition of blood; liver not secreting. Large gain in weight, due to rapid assimilation of food, owing to a great muscular waste. Large urinary excretion (1,950 c.c. in one day), due doubtless to almost total inactivity of sudorific glands.

TREATMENT OF CHOLERA IN INDIA.

By H. MARTYN SCUDDER, M.D.,

LATE MEDICAL MISSIONARY OF THE AMERICAN ARCOT MISSION, INDIA, CHICAGO, ILL.

For purposes of treatment I would divide the course of this disease into the following stages: A period of prodromes or prodromic stage; a first stage, or state of diarrhœa or chlorine; a second stage, or stage of invasion; a third stage, or stage of collapse (algid stage); a fourth stage, or stage of reaction. This last stage of reaction may be succeeded by a typhoid condition, or cholera typhoid stage, or else may pass directly into a state of convalescence. In the prodromic stage, manifested by lassitude, mental depression, chilliness, nausea, and abdominal discomfort, give ten or fifteen drops of spirits of camphor in dessert-spoonfuls of hot brandy every hour or two, but be careful not to allow any considerable quantity of stimulants to be taken. When epidemic cholera is prevalent many are affected by the symptoms just described. If the remedies I have indicated are promptly taken, I feel confident many attacks of cholera will be warded off. It is true that fear often produces these very symptoms, but the spirits of camphor in spoonfuls of warm brandy tends to soothe the fears and dissipate these symptoms, and yet does not usually disorder the digestion.

As soon as diarrhœa begins, the administration of some preparation of opium together with aromatics, camphor, and a little chloroform, is urgently called for. Two parts of "chlorodyne" to one of spirits of camphor is a very good combination, thirty drops for a dose. To be repeated as required. Another very serviceable prescription consists of equal parts of spirits of chloroform, spirits of camphor, laudanum, aromatic tincture of rhubarb, and tincture of ginger. Teaspoonful doses every hour or two according to the urgency of the case until four or five doses have been taken. In alternation with either of the combinations, an aromatic sulphuric acid mixture may be given to advantage. A popular formula is as follows:

℞. Acid. sulphuric. aromat... ℥ j.
Tinct. opii deodorat..... ℥ vj. vel ℥ j.

M. Sig.—Twenty or thirty drops in water every hour or two.

I think it important to administer these remedies

hot, unless they create nausea. The hot water, or morphine combined with chloral, should be administered by hypodermic injection, as the severity of the case may demand. Either of the following formulas may be chosen for exhibition every half hour or hour just after a spell of vomiting :

℞. Chloroform.,
Tinct. capsici,
Tinct. cannab. ind.....āā ♏ xxx.
Acid. hydrocyanic. dil..... ♏ xx.
Ether..... ♏ viij.
Spts. menthæ pip..... ♏ xv.
Syrup sassafras comp.....ad ℥ j.
Sig.—A small teaspoonful every half hour or hour.

℞. Spts. ammonia aromatic.,
Spts. of chloroform.....āā ℥ j.
Tinct. of capsicum,
Compound tinct. of cardamom,
Tinct. of ginger.....āā ℥ ss.
M. Give in the same doses as the above.

A mixture of aromatic powder, gum arabic, and acetate of lead may also be given alternately with either of these, if desired. In any case a mustard plaster should be applied over the stomach and abdomen, but not left on too long; and, if required, enemata of eight or ten grains of acetate of lead may be given after each evacuation. I think it is important to bear in mind that some preparation of opium or morphine, or morphia combined with chloral, is the chief remedy for cholera, and the surest agent we can use to arrest the progress of the disease. When called, therefore, to a case already in the stage of invasion, I believe morphine, or morphine and chloral, should be administered hypodermatically without delay, in order to get these sovereign remedies into the system as soon as possible ; for if we can arrest the disease before the patient becomes collapsed, his chances of recovery will be very greatly increased. Caution must be exercised, however, when this form of treatment is pursued, for narcotism is easily induced by repeated hypodermic injections, whereas very large doses of opiates can be given in this disease, by mouth and rectum, with comparative impunity. The strength of the solution usually employed for injection is morphine, gr. iijss. or gr. iv., with chloral hyd., ℥ ijss. or ℥ iij. to the ounce of water. Inject twenty or thirty minims.

The hypodermic use of morphine and chloral is, of course, contraindicated when the stage of collapse has become well developed. During this stage it is most essential that the patient should be kept perfectly quiet, and in the horizontal position. No violent rubbing should be allowed, but I have found it beneficial to gently rub the limbs and extremities with hot oil. To allay thirst let the patient suck ice frequently. Carbolic acid water or simple acidulated effervescing drinks may also be given by the tablespoonful. It is unsafe to allow the patient to drink any fluid whatsoever in large quantities. In this stage, especially when the acts of vomiting and purging have become less frequent and the algid state well developed, very small quantities of stimulants are useful, but they should be given with great caution, lest vomiting should be provoked. Stimulating enemata may also be given, but where the stomach is intolerant it is often better to inject small quantities hypodermatically. Experience teaches us, however, that anything like the free use of stimulants in cholera is uncalled for and exceedingly harmful. I have sometimes found small doses of both atropia and strychnia, administered by hypodermic injection, apparently effectual in bringing about reaction. Amyl nitrite, by inhalation, may be given, but it seems to exercise very little permanent beneficial effect. Intravenous administration of milk and salines may be resorted to, but the reaction thus produced is not generally of a permanent character, so that many of those who have given this method a fair trial have abandoned it.

Of late years, in Southern India, careful experiments have been carried out in reference to the value of impregnating the atmosphere of the sick room with sulphurous acid, by the burning of sulphur. The result has been that this procedure has been introduced as part of the treatment of cholera. I have on several occasions carefully tried this plan myself, by subjecting the inmates of two different cholera sheds to exactly the same conditions and treatment in every respect, with the exception that in one the atmosphere of the shed was kept impregnated with sulphurous acid, and in the other *not*. I have always found that the proportion of recoveries was considerably greater in the shed where sulphur was burned. I therefore now always proceed to burn sulphur in the patient's room, as part of the treatment of cholera, and consider it an important adjuvant.

The atmosphere should not be so highly impregnated as to cause the patient or attendants to cough violently.

Sulphurous acid thus applied is not only a useful remedy, but it is also believed to decrease the liability to the propagation of the disease, and to its contraction by the attendant.

During the stage of reaction, great care should be exercised. Vomiting often continues, and the normal absorbing power of the stomach and intestines is but slowly restored. Liquid nourishment by the spoonful should be most cautiously given; well salted broth and milk, given as hot as possible, and not too frequently, are the only forms of food admissible until the enfeebled stomach shows signs of recovering its tone. Peptonized beef-tea and milk are frequently well borne, if carefully prepared (two or three tablespoonfuls) Each dose may be sweetened, if desired. The patient should be made to lie down, kept perfectly quiet, covered with heated blankets, and dry heat applied to the surface of the body, especially to the extremities, by means of hot bottles, heated flat-irons, etc. In India the administration of calomel to any extent has lately been discouraged, one or two small doses may be given if thought best, but not more. As soon as frequent vomiting commences—or the stage of invasion becomes established, the combinations containing opium which have been mentioned, had better be discontinued, and either of the following mixtures given in teaspoonful doses at intervals, after a spell of vomiting.

At the same time, also, morphine, so as not to nauseate the patient. If vomiting persists, the following emulsion may be given, if deemed best :

℞. Acid. carbolic..... gr. vij.
Bismuth. subnit..... ℥ ij.
Mucil. acaciæ,
Aqua menth. virid..... āā ℥ j.
Sig.—A teaspoonful every hour or two.

But in this stage it is good treatment to let nature do the work of restoration, and give as little medicine as possible. We must have in mind, however, that the kidneys must be assisted to resume their functions, and for this purpose mild diuretics, such as potass. nitras, should be carefully administered. If fever supervenes, it is apt to be of a typhoid character : a combination of iodine and carbolic acid then exerts a beneficial effect. A popular formula is as follows :

℞. Acid. carbolic..... gr. iijss.
Tinct. iodi..... gtt. xv.
Aquæ menth. pip..... ℥ iv.
M. Sig.—A tablespoonful every two or three hours.

To relieve restlessness and insomnia, potass. bromid. is often useful.

If the attack of cholera is arrested before the patient becomes collapsed, the state of convalescence will probably be of short duration, and the health soon be restored. If, however, the patient is rescued after being in a profound state of collapse for a length of time, the convalescence will generally be protracted.

LARGE DOSES OF POTASSIUM OR SODIUM IODIDE IN SUDDEN DEAFNESS OF SUPPOSED SYPHILITIC ORIGIN.[1]

By ALBERT H. BUCK, M.D.,

NEW YORK.

The following very brief histories of cases are offered as a contribution to the subject of the daily administration—through a period of several days, or even weeks—of large doses of potassium or sodium iodide for the relief of sudden or rapidly developed deafness due apparently to the presence of syphilitic lesions in the labyrinth, or in some part of the auditory nerve outside of this system of cavities, or finally, in those parts of the tympanum which constitute the movable barriers of separation between this cavity and those of the labyrinth. I will add that I have been careful not to introduce among these cases any in which easily recognizable inflammatory lesions, presumably of syphilitic nature, were observed in the tympanum, or any in which, from the past history, it seemed probable that any such middle-ear lesions had been present at the time when the deafness developed. I have omitted such cases because nobody is disposed to doubt the curability of even very marked deafness when due to syphilitic lesions involving a large part of the tympanic mucous membrane, and interfering with the mechanism of the ossicles.[2] It would, therefore not be very profitable on the present occasion to report any such cases; particularly as my chief object in making this communication is to throw a little light, if I can, upon the prognosis and treatment of what appears to be syphilitic disease of the labyrinth, and at the same time to profit by the experience which other members of the Society may have had in the treatment of such cases, and which this communication, I trust, will lead them to publish. On the other hand, I have not thought it necessary to exclude one or two cases in which evidences of long-standing chronic catarrhal inflammation of the tympanum existed, but in which, at the time of my examination of the ear, no signs of congestion or swelling could be discovered. The profoundness of the deafness and the rapid manner in which it developed in these cases, are, it seems to me, characteristics of syphilitic disease of the auditory nerve rather than of catarrhal lesions in the tympanum.

There is still another point to which I must call attention. In the majority of the instances enumerated below, the grounds for suspecting syphilis to be the cause of the deafness seemed to be amply sufficient, but in a few the evidence in favor of such a conjectural diagnosis was certainly not strong. Indeed, in one case (Case IV.), there was no direct evidence that the patient had ever had this disease. His remarkable tolerance of the iodide of potassium (slowly increasing doses until finally 360 grains were taken daily for a period of one week) and the general resemblance of his attack to those of an acknowledged syphilitic nature, are the only grounds on which I can justify myself in placing this case in the same category with the others.

The literature of this particular subject is scanty. The attention of the profession was first called to it in 1877 by Dr. Roosa's report of a remarkable case in which, from a condition of almost total deafness, the patient's hearing within a few weeks was restored to nearly a normal condition.[3] A second, less striking instance, is reported by Dr. Roosa on page 526 of the same work. Beside these I can find only two other reports which throw light upon the employment of large doses of potassium iodide in the treatment of labyrinthine deafness, presumably of syphilitic origin, viz., those of Dr. Samuel Sexton[4] and Dr. David Webster.[5] In some of these cases, however, it is not perfectly clear that middle-ear lesions may not have contributed materially to the deafness.

From the strict standpoint of scientific inquiry it may be objected that no trustworthy deductions can be made from these published cases, or from those which I am about to report, with regard to the effects of the iodides upon syphilitic labyrinthine lesions, inasmuch as in all of them, with a single exception, mercury was administered at the same time. The objection is certainly a valid one; but, as an offset, I will say that, so far as I have any knowledge of the subject, no reports of success in the treatment of this class of cases have ever been published previously to 1877 (Dr. Roosa's report), that is, not until after the iodides had been administered in much larger doses than it had previously been customary to administer. From this circumstance, and from analogous experiences (on the part of others) in the treatment of syphilitic brain lesions, I think that we may properly ascribe to the iodides whatever curative phenomena have been observed in these few cases of sudden deafness.

Case I.—Male; thirty-eight years of age; first seen on October 25, 1880. He began to grow deaf about one year previously. Convulsions occurred at the onset. He was put at this time under ordinary anti-syphilitic treatment. Despite this, however, the hearing steadily and markedly diminished. Patient was very deaf at time of examination, which revealed no lesions adequate to explain the deafness. All that I know about the subsequent history of the case is comprised in the following extract from a letter written by the physician in attendance, Dr. C. McBurney: "Not very long after you saw the patient he developed mania, became very violent, and gave an immense amount of trouble in every way. This mania was doubtless dependent on some syphilitic lesion, and under the very large doses of iodide (several hundred grains daily) the mental disturbance disappeared. The deafness, however, was only slightly relieved."

Case II.—Male; twenty-seven years of age; patient seen for the first time on November 12, 1881. He gave a history of decided naso-pharyngeal catarrh and slowly increasing deafness since the age of fifteen. Eight or nine months ago syphilitic manifestations. Ten or twelve weeks later the deafness, which up to that time had not been very noticeable, became very marked, and at the time of my first examination it was so decided that I could make myself understood only by placing my lips close to the patient's right ear and fairly shouting into it what I had to say. In the left ear the deafness was apparently absolute. In the right ear there were evidences of a former, but now healed, otitis media purulenta (viz., a cicatricial reproduction of a part of the membrana tympani); in the left ear the membrana tympani was simply opaque in appearance and somewhat sunken. There was decided naso-pharyngeal catarrh, with the characteristic tone of voice. Eustachian tubes pervious to air. Hearing not affected by inflations. It not being clear to what extent the recent increase of deafness might be due to the naso-pharyngeal catarrh, I directed treatment toward the relief of this affection as well as toward the constitutional syphilis. On the one hand, I applied a solution of nitrate of silver (twenty grains to the ounce) to the affected mucous membrane of the naso-pharynx three times a week; and for the anti-syphilitic part of the treatment I recommended daily inunctions of a five per cent. preparation of Squibb's oleate of mercury, and the internal administration of the iodide of potassium, three times daily, in increasing doses.

On December 8th the patient's gums began to be noticeably affected, and the inunctions were accordingly discontinued.

On December 17th he began to complain of great lassitude. He was then taking daily only thirty grains of the iodide of potassium and three grains of the sesqui-

[1] A paper read before the American Otological Society, July 15, 1884.

[5] Archives of Otology, vol. xii.

carbonate of ammonia. As his face also wore a haggard look, I advised him to stop all treatment for a few days.

On December 27th the iodide of potassium treatment was resumed; the sesquicarbonate of ammonia being omitted from the mixture. Numerous small ulcers visible on the gums.

December 30th.—Forty-five grains of the iodide of potassium daily. The local applications to the vault of the pharynx were discontinued about this time.

January 4, 1882.—Fifty-five grains daily. An eruption of small pustules has broken out on his face and shoulders.

January 10th.—Complains of a "cold in the head."

January 13th.—Sixty-five grains daily. He complains of headache, a sensation of soreness in the back, sore throat, a very free discharge from the nose, frequent sneezing, and an occasional attack of coughing. A brief suspension of the treatment advised.

January 14th.—Two decided chills with marked prostration occurred during the night. This morning he looks pale and haggard, and complains of a sense of discomfort in the abdominal region. I prescribed a mixture of the ammonio-citrate of iron and the compound tincture of cinchona, each dose containing two grains of the former and one drachm of the latter.

January 17th.—The iron and cinchona mixture soon produced a decided ringing in his ears, and he discontinued it. All the other unpleasant symptoms, however, have disappeared, and he feels comparatively well again. The hearing, too, of late, has noticeably improved. At times he has been able to understand sentences spoken in an ordinary tone of voice at a distance of four or five feet from his right ear. The improvement, however, has never lasted longer than a few hours, or at most a day, at a time. To-day I am able, sitting directly in front of him, at a distance of from two to three feet, to make myself understood by simply raising my voice slightly. He does not appear to read my lips; in fact they are concealed by my mustache.

January 18th.—At the suggestion of Dr. F. R. Sturgis, of this city, who saw the case in consultation with me, I prescribed a saturated solution of the iodide of potassium (1 minim, = about 1 grain). Of this solution the patient was instructed to take fifteen minims three times a day, after his meals, and afterward to increase the dose on the alternate days by five minims. Thus, for example, it was intended that he should take 45 minims a day on January 19th and 20th, 60 minims on the 21st and 22d, 75 minims on the 23d and 24th, and so on.

January 31st.—He is now taking 120 minims daily without any discomfort whatever. Appetite good. A few insignificant pimples are still visible on his face. During the coming week he is to discontinue the iodide of potassium, and in its stead to take daily a drachm and a half of the syrup of the iodide of iron.

February 6th.—Potassium iodide resumed: 120 minims daily.

February 18th.—One hundred and ninety-five minims daily. The papular eruption on the patient's face is now quite noticeable. He is again to discontinue the remedy for one week, and to take the iodide of iron instead. A still further improvement has taken place in the hearing. I can now converse with him at a distance of at least four or five feet; my pitch of voice being as nearly as possible the same as when I tested the hearing on January 17th.

February 24th.—One hundred and ninety-five minims daily.

March 3d.—Two hundred and forty minims daily. No discomfort whatever from the remedy. Hearing distance has increased to seven feet. Iodide of iron substituted for a few days.

March 8th.—Two hundred and forty minims.

March 12th.—Two hundred and seventy minims.

March 13th.—Patient is totally deaf this morning, the result, apparently, of a cold which he contracted last evening. Marked hoarseness. Right Eustachian tube obstructed, and right membrana tympani markedly sunken. Inflations by Politzer's method and naso-pharyngeal treatment to be resumed. The iodide of potassium to be discontinued.

March 20th.—The hearing is again as good as it was on March 3d. Two hundred and seventy minims to be taken to-day.

March 24th.—Three hundred minims.

April 28th.—Three hundred and forty-five minims.

May 15th.—Four hundred and eighty minims.

May 22d.—Five hundred and twenty-five minims.

May 24th.—General malaise. Hearing again quite poor. Numerous small ulcers on gums, on inner surface of lips, and on frenum of tongue. Nitrate of silver (solid) applied to each. The iodide of potassium treatment to be abandoned.

July 6th.—Patient writes from his home in the country that the ulcers have healed, and that his general health is again perfectly good. His hearing, however, remains poor.

The last report which I received was dated September 11th. The ulcers had reappeared on his gums and lips toward the end of July, and he had suffered more or less from "malaria" during this period of nine or ten weeks. At one time the hearing had been even better than it was in New York during the previous month of March. It soon diminished again, however, and was, at the date of his letter, about as bad as when I first saw him.

Case III.—Male; forty-five years of age; February 24, 1882. Deafness began to develop four years previously, and in about two years it had become so marked that it was only with great difficulty that he could hear what was said to him. During the past two years the hearing had remained unchanged. Syphilitic manifestations twenty-five years previously. He had also, up to a comparatively recent date, used alcoholic stimulants to excess. Recently he had had some difficulty with his eyesight, and there had been some paresis of the muscles of the lower extremities.

Treatment (by Dr. E. D. Hudson, Jr., of this city): inunctions with a five per cent. Squibb's oleate of mercury, and increasing doses of the iodide of potassium; beginning with five minims of a saturated solution, to be taken three times daily, and the dose to be increased by five minims on alternate days.

On April 6th his gums began to be affected, and the inunctions were discontinued. Two hundred and eighty-five minims of the iodide of potassium solution taken daily. No eruption. No coryza. No discomfort of any kind.

April 12th.—Three hundred and fifteen minims. No improvement in the hearing.

April 20th.—Potassium iodide discontinued during the past week, but now to be resumed.

May 4th.—He has taken 315 minims daily during the past two weeks, without any unpleasant effects, but also without any appreciable improvement in the condition of the hearing.

Treatment abandoned.

Case IV.—Male; fifty-two years of age; robust health; professional musician (wind instrument); November 2, 1883. Patient had been somewhat hard of hearing since 1877. In the left ear the hearing power had been almost, if not quite, destroyed, but with the right ear he had been able to hear fairly well—well enough for all ordinary purposes of daily life. On October 27th he began to grow quite deaf in the right ear, and in less than forty-eight hours he had entirely lost the hearing in that ear. There was an entire absence of anything like vertigo, but the tinnitus was very marked, and extremely distressing. He spoke of it as a terrible rushing sound in his ear. At the time when I saw him (November 2d) I was obliged to communicate with him in writing, as he was apparently perfectly deaf in both ears. Both middle ears and external auditory canals seemed to be essentially normal. No history of syphilis.

At first I was disposed to look upon the deafness as due to the rupture of a blood-vessel and the escape of blood into the labyrinth. On this supposition I had three leeches applied immediately to the region of the right tragus, and advised the promotion of free after-bleeding. A blister was also applied behind the ear, and four or five days later a second one was applied at the same spot. No beneficial effects following these measures, I prescribed a saturated solution of the iodide of sodium. Of this he took at first 30 minims daily, and then gradually increased the dose, until, from December 18th to December 24th, he took daily 360 minims. He experienced no unpleasant symptoms from the large doses beyond a scanty eruption on his forehead, and some general malaise toward the end of this period. The hearing, however, was not restored in the slightest degree, and the tinnitus was not appreciably diminished. Treatment then abandoned.

Case V.—Male; forty years of age; apparently in robust health (patient of Drs. George A. Peters and Wm. A. Valentine); May 24, 1884. Two days previously he had experienced decided vertigo, nausea, and double tinnitus. In a short time vomiting of mucus and bile set in, and continued, at intervals, for several hours. He then made the discovery that he had entirely lost the hearing power of both ears. Examination of the ears revealed no lesions other than those of a chronic catarrhal inflammation of both tympana. He declared that he could hear the ticking of my watch in his right ear, but he was not able to distinguish spoken words.

As the patient had been under my care ten years previously for syphilitic sore throat with subacute otitis media, I advised a trial of the mixed treatment described above.

May 28th.—The vertigo has largely disappeared, and patient says that he can understand what his wife says to him in a loud, shrill voice.

On July 7th I learned from Dr. Valentine that little or no improvement had taken place in the hearing, that the tinnitus was still marked, and that he could not as yet walk steadily. Up to that time he had not been able to take more than 90 grains of the iodide of potassium daily. It was found that he could take this more comfortably than he could the iodide of sodium, which nauseated him.

July 14th.—Patient has been taking 180 grains daily, but without any effect upon the hearing. On the 11th the treatment was suspended, as patient's stomach began to rebel.

Soon afterward the treatment was resumed, and before the end of the month the daily quantity of potassium iodide taken by the patient had reached 270 grains. He had taken this quantity daily for a period of one week, when it was found necessary to stop the treatment altogether, as his general condition showed that it was doing him more harm than good. It certainly produced little or no effect upon the hearing power, as it was still found necessary to communicate with him in writing.

It is not possible to draw any very satisfactory conclusion from such a small number of cases. For example, the treatment failed to accomplish anything worthy the name of improvement in all five instances, and yet, as has been observed in the cases reported by Dr. Roosa, and in those reported by Dr. Webster, essentially the same treatment may accomplish strikingly favorable results. I have compared these cases very carefully with those reported above, in the hope that I might find out certain distinguishing features which would enable us to divide all such cases into two classes, viz., those which might be benefited by treatment, and those in which treatment would almost certainly fail. I have not, however, been able to find any such distinguishing characteristics. The only plausible explanation that I can give of the infrequency of our successes is this: A syphilitic gumma in the labyrinth, and especially in the cochlea, will rarely fail to produce damage from which recovery is scarcely possible. Treatment may lead to the absorption of the gumma, but it cannot readjust and render functionally useful those delicate and carefully adjusted organs which the tumor has disarranged, and perhaps even destroyed. In the brain excellent compensatory provision seems to have been made for the pressure caused by a gumma or other morbid growth; in the labyrinth, on the other hand, the rigidity of the surrounding walls and the paucity as well as smallness of the blood-vessels, almost preclude the possibility of compensation. On physiological grounds, therefore, I feel confident that such cures as those reported by Dr. Roosa and Dr. Webster will always be exceptional. In these cases we may assume that the pressure had gone only so far as to suspend for a time the vibratory power of the cochlear structures, but had not destroyed or even seriously disarranged them. It is also possible that the gumma may occupy a position in the vicinity of the oval window and foot-plate of the stirrup, or in that of the secondary tympanic membrane. A lesion so situated would be competent to annul the power of hearing, but it would not necessarily destroy it.

In the next place, it will be observed that in the favorable cases the improvement began to show itself as early as during the second or third week of the iodide of potassium treatment. This would suggest the question whether it is really necessary to push the doses to the extreme limits recorded above (viz., 270 gr., 315 gr., 360 gr., 525 gr., and "several hundred grains" daily). This is a question which cannot be satisfactorily answered until we shall have accumulated a greater array of evidence. I am disposed, however, to adopt for the present the rule of not giving more than from one to two drachms daily in those cases in which commencing improvement is observed during the second or third week of treatment.

In conclusion, I will state that in the first years of practice I must have registered some cases of syphilitic disease of the labyrinth as instances of "Ménière's disease," and I believe that this error—if error it be—has probably been committed by other specialists.

HAY ASTHMA—CAN IT BE RELIEVED?

By WILLIAM JUDKINS, M.D.,

LATE PROFESSOR OF PHYSIOLOGY, ETC., CINCINNATI COLLEGE OF MEDICINE AND SURGERY, CINCINNATI, O.

I FEEL that I should be sadly derelict of duty did I not give to the profession, and through them to the laity, my successful treatment of this obstinate and distressing complaint. Though only the record of one case, the result is so gratifying to the patient, her family, and myself, that I feel justified in sending these few lines regarding it, in hope of benefiting others.

Mrs. ——, aged twenty-eight, married, mother of two children, the youngest four and a half months old. Has been subject to an annual attack of hay fever for fourteen years, and frequently with complications of a severe character. Last year she suffered an attack of bronchitis during the latter part of the asthmatic stage, that came near proving fatal. Convalescence slow. This case first came under my charge in 1880. The attack that year was aggravated in a measure by pregnancy. The only thing at that time that gave any relief was "milk punch," in the proportion of whiskey, 2 oz.; milk, 8 oz. The relief obtained from this was only temporary, when more would be administered; but at no time was intoxication produced, though the remedy was given for several days in succession. In 1881 a reputed "hay-fever resort"—Oakland, Md.—was tried for a part of the season, but no benefit was derived, the attack being fully as severe as at any previous time. 1882 and 1883 were equally as bad, the complication of bronchitis spoken of above coming on last year, which almost caused death. This year prophylactic treatment was commenced, some two weeks before her expected attack, of valerianate of

zinc, gr. i., and pill assafœtida co., gr. ii., combined in capsules, one A.M. and P.M., as recommended by Dr. Morell Mackenzie, of London. It disagreed with her stomach, and was discontinued for three days and then again taken with no bad effect. For five days after her usual time for the appearance of the dreaded affection all was serene. The night of the 20th inst. difficulty of breathing to a limited extent set in. My attention had been called to a case of bronchial asthma, who obtained relief from the use of acid hydriodic, and I immediately ordered my patient to commence its use early on the morning of the next day, the 21st. The effect, in conjunction with counter-irritation in the shape of Rigollot's mustard leaves at the wrist-joints, *was simply magical*, breathing became more and more easy as she continued the remedies. A thunder-storm came up that night, twelve hours after commencing the medicine, and for half an hour she was somewhat "stuffed up," as she expressed it, but had a good night's rest. Ever since then she has been easy—now a week—but is exercising all precautionary measures against taking cold, for fear of a relapse.

I can truly say that about every remedy suggested and recommended from the time that Bostock first wrote on the subject, in 1819, had been tried, but nothing has ever given the relief and sense of comfort that this did. One word more and I am done: the form of administration was that of the syrup—a teaspoonful every hour or two, until relief. If necessary double the dose. The syrup, as prepared by Mr. Gardner—Schieffelin & Co.'s chemist—was the special brand, though where that is not accessible, I imagine the regular acid of the dispensatory on a lump of sugar, gtt. 3 to 5, would be equally as efficacious. The mustard leaves are applied as soon as the first dose is given.

Since commencing the acid treatment, my brother, Dr. C. P. Judkins, has prescribed it in another case, that of a married lady who suffered intensely with the asthmatic symptoms, with perfect relief, that so far has been continuous, and as in my own patient, bids fair to continue so.

The capsules were discontinued when commencing the use of the acid.

216 RACE STREET, August 28, 1884.

THE DISCUSSION ON CHOLERA AND THE COMMA-BACILLUS IN THE BERLIN CONFERENCE.

WE gave last week an abstract of Dr. Koch's lecture on cholera and the comma-bacillus, delivered at the Imperial Board of Health, in Berlin. After describing the bacillus and its relation to cholera, he spoke of the conditions under which it thrives in its home in India. Southern Bengal is a flat country, elevated but little above the level of the sea, and is almost completely submerged during the rainy season. In order to escape the flood, the inhabitants build their houses on artificial elevations, made by piling up the earth taken from the side of the foundation. It thus happens that beside every house or group of houses there is a large hole filled with water. These tanks, as they are called, are very numerous, there being a thousand or more in the suburbs of Calcutta alone. The huts of the natives have no privies attached, and every kind of dirt is thown directly on the ground, from whence it finds its way naturally, into the neighboring tanks. A system of sewerage was introduced in 1865, and at the same time measures were taken to furnish the city with filtered water brought from the river some miles above Calcutta. No improvement in the health of the city was noticed during the first few years that the canal system was being extended, but as soon as the pure water supply was obtained, in 1870, the cholera decreased, and the death-rate from this cause has not since then surpassed, on an average, one-third of its former figures. In the suburbs, between which and the city there is a constant intercourse, but to which the water supply has not been extended, the cholera is as prevalent as before. Similar and even more striking instances of the influence of the water supply were furnished by other cities and places in India. These cases were cited to show the value of pure water, but Dr. Koch did not wish to be considered a partisan of an exclusive drinking-water theory, for he thought that cholera might be propagated in many different ways in any particular locality, and further, that each locality had its own peculiar conditions favorable to the spread of the disease.

In former times the cholera travelled along the caravan routes from India through Persia and thence into southern Europe, but now it takes the more speedy way through the Red Sea and the Suez Canal. There is little likelihood in these times of the disease coming overland, but the danger of its introduction by way of the Red Sea is becoming greater every year. From Bombay, which is seldom free from cholera, to Egypt is a matter of only eleven days, to Italy sixteen days, and not more than twenty days, at the most, to the South of France. As regards the danger of the transportation of cholera in ships, however, much depends upon the character of the vessel. Epidemics occur only on those ships in which large numbers of men are crowded together. In merchant vessels and freighters, although there may be a few cases of cholera during the first days of the voyage, the disease never becomes epidemic nor continues for a long time.

In concluding, the lecturer spoke briefly of the value of the discovery of the cholera bacillus. In the first place, it is of the greatest importance to be able to diagnose correctly the first case of cholera occurring in a country or in any locality. This, he believed, could now be done with absolute certainty if the comma-bacillus were found in the dejections. And further, when the cause of a disease and its properties are thoroughly understood, we are in condition to determine with accuracy its etiological relations, and also to institute a rational and effectual mode of treatment. Not the least important consideration is the hope, now offered, of discovering a certain means of prophylaxis.

At the close of Dr. Koch's lecture, Professor Virchow announced that a second conference would be held on the evening of July 29th for the purpose of discussing the various points suggested by the paper.

After the members had re-assembled, Professor Virchow stated that in order to keep the discussion within bounds, certain questions had been prepared, covering all the points raised in the lecture, upon which those present were requested to express their views. The first question was:

IS CHOLERA CAUSED BY AN INFECTIOUS MATERIAL ORIGINATING ONLY IN INDIA?

This was answered in the affirmative. Herr Hirsch said that in the Sanitary Conference, held in Vienna in 1874, the members were unanimous in the opinion that cholera occurs in Europe in consequuence only of the introduction of the specific poison from India. This unanimity was the more noteworthy as on other questions relating to cholera there were many conflicting opinions expressed by the delegates.

The next question proposed for discussion was:

IS THE INFECTIOUS MATERIAL CONTAINED ONLY IN THE DEJECTIONS, AND LATER ALSO IN THE VOMITED MATTERS, OR IS IT FOUND ALSO IN THE BLOOD, URINE, SWEAT, AND EXPIRED AIR?

Dr. Koch stated that it was his firm conviction that the cholera poison was present in the dejections only. In exceptional cases it was found in the vomited matters, but only when these matters were of intestinal origin.

The two following points were considered together:

IS THE PRESENCE OF THE COMMA-BACILLUS OF DIAGNOSTIC IMPORT? AND, IS THE INFECTIOUS MATERIAL OF CHOLERA IDENTICAL WITH THE COMMA-BACILLUS?

Professor Virchow said that, in regard to the second point, some elements of absolute certainty were wanting. On the one hand, no one had as yet succeeded in producing cholera in the lower animals by inoculation with the comma-bacillus. Dr. Richards had indeed fed hogs upon intestinal matters taken from cholera patients, and the animals had sickened and died, but Dr. Koch maintained that death in these cases was caused by poisoning and that the disease produced was not cholera. He thought it very desirable that comparative experiments should be made with pure cultures of the comma-bacillus and with the cholera dejections, for at present it seemed possible that there might be some other infectious material in addition to the bacillus. On the other hand, the whole history of cholera, its mode of origin and spread, seemed inexplicable, except upon the theory of a living contagium. And among all the micro-organisms found in the cholera stools the comma-bacillus alone could with any degree of probability be accused of causing the disease. The question whether there was any other disease in which this particular micro-organism was present could not yet be answered with certainty, and indeed, it might be many years before it could be affirmed or denied with strictly scientific accuracy. But for the present the speaker thought that it was incumbent upon the sanitary authorities to act as though the comma-bacillus was the actual and certain cause of cholera.

Dr. Koch remarked that his reason for believing that the hogs in Dr. Richards' experiment were poisoned, was that they died so speedily, within two and a half hours. And then every attempt at a reproduction of the infectious material in these cases failed. He thought, however, that the experiments told in no way against the bacillus theory; on the contrary, they showed that a poisonous substance was formed in the intestinal canal under the influence of the comma-bacillus. In regard to a point suggested by Dr. Hirsch, the speaker said that he had examined sections of the intestinal mucous membrane taken from a man dead of cholera morbus, but had found no comma-bacilli, although there were swarms of other micro-organisms present. In answer to a question asked by Professor Virchow, whether in a doubtful case, presenting the symptoms of either cholera morbus or Asiatic cholera, but in which simple microscopic examination of the stools had revealed the presence of countless comma-bacilli, he would hesitate to make a diagnosis. Dr. Koch asserted emphatically that he would not. He said, however, that it was seldom possible to find the micro-organisms in great numbers in a microscopical examination of the dejections. In most cases the culture method is necessary, and this never fails. This question of an early diagnosis of cholera, he continued, is a very important one indeed, for if the first case in any locality be recognized immediately, it can be isolated, and thus the spread of the disease be prevented. But if the diagnosis be delayed until half a dozen or more cases have occurred, then all control over the outbreak is lost. Regarding the difficulties of a general use of this method, he had only to say that the process of staining the tubercle bacilli, which was now very generally understood, was far more difficult than was that of cultivating the comma-bacillus. In answer to an inquiry of Dr. Schubert, he said that he had found the bacilli present very early in the disease, within a few hours, and he could state positively that the first colorless watery stools contained them in great numbers. Another hypothetical question was proposed, whether in the case of a person coming from a cholera district and presenting symptoms of cholera, but in whose stools no comma-bacilli could be detected, the patient should be allowed to go where he would or should be kept under observation? To this the speaker replied that the case ought certainly to be regarded as a very suspicious one. But this was not exactly a case in point. A person, known to have come directly from a cholera infested region, who shall be taken ill with symptoms of cholera, ought to be isolated at once, there would be no necessity of searching for the comma-bacillus. But to suppose a case. Cholera is now ravaging the south of France. A case with symptoms resembling those of cholera occurs suddenly in a German city, and comma-bacilli are found in the dejections. Now, the cholera poison is already in the city, and much more active measures must be taken than simply to bury the corpse and disinfect the surroundings.

It having been objected that the culture of the comma-bacillus required a well-appointed laboratory, and the possession of considerable skill and experience on the part of the physician, Dr. Koch explained the method employed by him. The gelatine used could now be bought in the shops. All that was necessary was to warm the gelatine, mix it with a flocculus of mucus from the stools, and then pour it out on a piece of glass. This is then placed under a glass bell, or, if the latter cannot be had, between two plates, as was done in the experiments made in Calcutta. It is easy enough to obtain material for examination, for any of the clothes soiled with the passages will furnish enough mucous flocculi for the purpose. A special warming apparatus is not necessary, for the ordinary summer temperature was over 17° C. (62.6° F.), which was sufficient for the development of the bacilli.

The next two questions proposed were:

DOES THE INFECTIOUS MATERIAL POSSESS A GREAT POWER OF RESISTANCE, HAS IT A STAGE OF PERMANENCE? AND, IS IT DESTROYED IN A SHORT TIME BY DRYING?

Dr. Koch said that his opinion on this point was based not only upon his experiments with the comma-bacillus, but also upon the universal experience with cholera. There was no case known with certainty in which the poison of cholera had remained latent for a great length of time, and had then renewed its activity.

Dr. Hirsch related his experience in the cholera epidemic which had visited Posen and West Prussia in 1873. He had seen many cases in which the first persons attacked in a village were women who had washed soiled clothing brought from infected districts. In several of these cases the clothes were allowed to remain some time untouched, before being unpacked and cleaned.

In reply to a question of Dr. Koch he said that the clothes in some cases were left for five or six days, long enough for them to become thoroughly dry. It had been admitted by the lecturer, he continued, that under conditions of moisture the comma-bacillus might remain latent for an almost unlimited period. Why, then, was it not possible, in a place where cholera had been epidemic, for the bacillus to remain alive in moist earth or other damp places during such time as the other conditions were not favorable to its development, and then to become active and give occasion to a new epidemic as soon as a favorable conjunction of circumstances should arise?

Dr. Koch said that he had admitted the possibility of such an occurrence, after having found that the comma-bacillus could endure a very low temperature and could exist outside of the human body, in potato, gelatine, and damp clothing, for example, for an indefinite time. He thought the question a very important one but which the future only could solve. The ground, the water, and everything that could offer an asylum to the bacillus ought to be examined for a long time after the disappearance of cholera from a place. Such investigations could not be made in India, because the cholera was always there, but could be undertaken upon the subsidence of an epidemic in Europe.

The next question proposed for discussion was:

CAN THE INFECTIOUS MATERIAL ENTER THE BODY BY OTHER CHANNELS THAN THE DIGESTIVE TRACT?

The discussion was not confined strictly to this point, but turned rather upon the question whether the infectious material could be transported through the air. Several of those present thought that it might be so carried, at least for short distances, and instanced the frequency with which those who handled the bodies of persons dead of cholera were themselves attacked with the disease. Dr. Leyden thought it very possible for the germs to be carried up into the air with fine particles of moisture during the rapid evaporation of contaminated fluid.

These views were very strongly opposed by Dr. Koch. He thought it much more probable that the disease occurring in those who handled the corpses of cholera patients was due to a want of cleanliness on the part of those individuals. Their hands became soiled and then they took food without washing. The physicians and nurses in hospitals who were careful in washing themselves were no more liable to cholera than other people, and yet, if the poison were carried through the air, they ought to be among the principal sufferers. The cholera bacillus was killed by drying, and it could be carried through the air only in watery spray or in bubbles; in dust it could not live. In regard to cases in which the disease was alleged to have been carried by healthy individuals, the explanation would probably be simplified were all the circumstances known. Very possibly food or other articles were carried from the house of the cholera patient, or the apparently healthy individual might have had a very mild attack of cholera which passed unnoticed.

IS THE INFECTIOUS MATERIAL REPRODUCED IN THE HUMAN SUBJECT, OR DOES THIS TAKE PLACE IN THE GROUND, SO THAT MEN ACT ONLY AS CARRIERS OF IT?

Professor Virchow asked whether, since the comma-bacillus was an air-breathing organism, the intestinal canal could be regarded as a favorable location for its development.

Dr. Koch said that either free oxygen must be present in the intestine, or at least such combinations must be there as would give off oxygen. For we see the bacilli living in great numbers in the intestine, and yet they cease to grow outside of the body when deprived of air. Consequently they must in some way obtain oxygen in the intestine. Other organisms which require oxygen for their existence, as the *oidium lactis* for example, are often found in quantities in the intestinal canal.

Professor Virchow thought it probable that the bacillus was reproduced both outside and inside the human organism. At least it was shown that the reproduction in the ground was possible, but further than that we could not yet go.

The next question proposed was:

IS A DIRECT TRANSPLANTATION POSSIBLE, OR MUST THE INFECTIOUS MATERIAL UNDERGO A SORT OF RIPENING OR GROWTH IN THE GROUND OR ELSEWHERE?

It was supposed, Dr. Koch said, that a sort of ripening of the cholera germ was necessary, because the dejections were not infectious when first passed. This latter assertion was based upon an experiment of Thiersch, but his own opinion was that the clothes were capable of transmitting the disease at the very instant that they became soiled.

Three questions were then presented, embracing the subject of the trasmission of cholera by clothing, rags, merchandise, food, etc. Dr. Skrzeczka thought it very reasonable to suppose that the disease-germs could be carried in rags, for these were packed in large bales, and if the rags were not thoroughly dried, those in the centre of the bale might remain moist for an indefinite period.

Dr. Koch answered that this question of the possibility of infection through rags was discussed in the cholera congresses of Vienna and Constantinople, and nobody was able to furnish an instance of the spread of the disease by this means. The rags should, he thought, be thoroughly dried before being packed. But it seemed to be of little use to prevent the importation of rags, if human intercourse was to be allowed. The danger of the introduction of cholera through apparently healthy individuals, a danger which cannot be guarded against, is far greater than that of transmitting the disease by rags. As regards water he said that, as far as his experience went, the comma-bacilli die in clean water, not immediately, but within a few days.

The remaining questions were:

IS A SPECIAL INDIVIDUAL PREDISPOSITION NECESSARY FOR THE ACTION OF THE INFECTIOUS MATERIAL? WHAT IS THE PERIOD OF INCUBATION? DOES ONE ATTACK CONFER IMMUNITY FOR A CERTAIN LENGTH OF TIME? AND, CAN THE MODE OF ACTION OF THE BACILLI BE REGARDED AS A POISONING?

Dr. Leyden thought that one attack did confer a degree of immunity against subsequent attacks, yet this immunity was not absolute, for cases had been reported in which an individual had suffered from cholera several times during the same epidemic.

Dr. Hirsch stated that in the epidemic studied by him, in 1873, the period of incubation seemed to vary between two and four days.

Professor Virchow then closed the discussion by tendering his thanks to Dr. Koch for the lucid report which he had given of his studies of the comma-bacillus, and he said that the members would probably be called together again to discuss these questions, and to impart any new experiences which they might have gained in regard to the prevention or cure of cholera.

PERNICIOUS MALARIAL ATTACKS OF UNUSUAL TYPE.—The following are the conclusions of a paper read by Dr. Besnier at a recent meeting of the Société de Médecine de Paris (*L'Union Médicale*, July 26, 1884): 1. Certain chronic diseases or morbid conditions, existing prior to the malarial attack, and giving rise in their course to more or less grave secondary symptoms, or manifesting themselves by repeated functional disturbances, may sometimes so influence an intermittent fever as to render it abnormal or pernicious. 2. In such cases the form of the pernicious attack is in direct relation with the antecedent disease. It resembles in its prominent symptoms one or other of the secondary accidents or the functional troubles of this disease, but in an aggravated degree. The attack is thus more or less masked by the antecedent malady and may readily escape recognition. 3. The morbid states which precede the fever and which impress upon it their form, may be very slight and compatible with all the exigencies of ordinary life. The malaria, on the other hand, may have been contracted in an infected region and may reveal itself for the first time long after the patient has left that country. The pernicious attack may thus be more insidious and more sudden in its onset than are malarial fevers ordinarily. 4. These pernicious paroxysms owe their gravity apparently less to the malaria than to the antecedent disease upon which the malaria has engrafted itself. They occur with perhaps greater frequency in non-malarious regions. They yield, as a rule, readily to quinine, even in moderate doses. The antecedent affections in the cases studied by Dr. Besnier, and upon which he based his conclusions, were: arterial atheroma with encephalic troubles, diabetes accompanied with albuminuria, and angina pectoris. The pernicious paroxysms assumed three very distinct types: a delirious, a comatose, and a cardialgic form.

Reports of Hospitals.

ROOSEVELT HOSPITAL, NEW YORK.

Reported by J. E. NEWCOMB, M.D.,
HOUSE PHYSICIAN, ROOSEVELT HOSPITAL.

The following notes, taken from the hospital records, narrate the history of

A CASE IN WHICH ALL THE SIGNS AND SYMPTOMS OF AORTIC ANEURISM WERE SIMULATED BY AN ENORMOUSLY DILATED HEART

with double aortic valvular lesion.

Thomas K——, New York, single, laborer, aged sixteen, was admitted on August 3, 1881. Father died six years before of hæmoptysis, and mother one year before of uterine cancer. Patient was temperate, denied syphilis, admitted occasional masturbation and sexual intercourse. Had rheumatism three years ago; developed therewith pain in epigastric and præcordial regions, and has been subject to it ever since. For last year has noticed increasing cardiac palpitation and dyspnœa. No œdema; vision at times dimmed; cough for past three months very severe, of late worse mornings and evenings; muco-purulent sputa; quite regular night-sweats for past month; no hæmoptysis; occasional vomiting after meals; some emaciation; bowels usually regular; no urinary changes noted.

On admission rather poorly nourished, weak and tremulous; countenance downcast; face sunburnt, but cyanosed; marked dyspnœa, least troublesome in sitting position; loose cough, with copious muco-purulent expectoration. Cannot sleep on left side; good appetite; some constipation. Urine 1.026; acid; no albumen; microscopic examination negative.

Physical examination.—Heart-apex, sixth space, one inch outside nipple line; impulse strong, heaving, and raising considerable area of chest-wall. Dulness on level of third rib from right border of sternum to half an inch inside left nipple line. Over first and second right interspaces, close to sternum, is an area of dulness; over it is felt a systolic thrill and heard a loud, rasping, systolic murmur, with soft diastolic murmur of lower pitch. A systolic murmur is heard in carotids and subclavians, about equally clearly on both sides; is heard over sternum down to level of third right costo-sternal articulation, where it suddenly becomes softer in character, while at the same time the diastolic murmur heard in its upper interspaces becomes much louder and sharper; latter transmitted down to xiphoid cartilage. At apex is heard a short, blowing systolic murmur transmitted to left, heard behind in both vertebral grooves, louder in left, and as low down as the last dorsal vertebra. A very distinct double murmur is heard in the right supra-spinous fossa. The radial pulse has a rapid rise and fall, with a peculiar "shot"-like effect when hand is elevated above head. Visible pulsation in all superficial arteries of any size. Lungs at right apex, markedly exaggerated voice and breathing, otherwise breathing is feeble everywhere; subcrepitant râles all over chest. A diagnosis was made of aneurism of ascending arch of aorta with aortic insufficiency.

The patient remained in the hospital for about eight months. The details of treatment need not be gone into. Reliance was chiefly placed on digitalis and iodide of potash, the dosage being varied from time to time to suit the requirements of the case. A fortnight after admission he began to have bloody sputa, which continued for some time; later, attacks of spasmodic dyspnœa came on, which were promptly relieved by small hypodermics of Magendie's solution. Ten weeks after admission he began to have nocturnal dyspnœa, with anginoid pain in præcordium and left shoulder, running down arm to elbow. These attacks were sometimes cut short by inhalations of amyl nitrite, and later by internal exhibition of one drop of a one per cent. solution of nitroglycerine. At other times these remedies seemed to have no effect whatever. A month later the arm pain was accompanied by temporary paralysis of entire extremity. Four months after admission a marked thrill and visible pulsation were noted in carotids and over sternum.

The patient was discharged, improved, on April 6, 1882. During preceding two months had had only two dyspnœal attacks. The severity of all the symptoms was greatly abated, though the physical signs remained practically the same. After leaving the hospital he resumed work as an iceman and passed out from under observation. On June 21, 1884, he again presented himself—having enjoyed fair health in the interim, excepting that the cough had steadily persisted. Two weeks before, he caught cold, increasing the cough, and causing orthopnœa, with occasional vomiting after coughing severely. He had scanty muco-purulent sputa, pain in right chest, anorexia, with cramps in belly and calves of legs. Cardiac action was hurried, averaging 120 per minute. Respiration 40 and very labored; evening temperature (mouth), 102.8°; morning, 99.8°; urine, 1.030, no albumen, but hyaline and epithelial casts. Contrasting his present physical condition with that twenty-two months ago, the following points of difference were noted: The heart-apex was in sixth space, three inches below the nipple and five in left of mid-sternal line. On level of the third rib dulness extended from half an inch to the right of sternum to one inch outside left nipple. The area of dulness in the right upper interspaces had extended to third space, and over it was a visible pulsation with marked purring systolic thrill and rasping bruit; the finger placed in supra-sternal notch received a distinct lift at each cardiac pulsation; there was a general bulging forward of the entire chest. The appearance of a localized pulsation over the area of dulness in the right spaces was considered as verification of the previous diagnosis. He was ordered milk diet with ten grains of iodide of potash t.i.d. His dyspnœa continued, but was quite well controlled by small doses of opium. On June 24th had profuse sweating with some dysuria. Next day anginoid pain in abdomen returned, but was quieted by six minims of Magendie hypodermically. Early on the morning of the 27th, while sitting on the side of the bed in the act of voiding urine, suddenly he slid down to the floor, grew cyanotic, radial pulse ceased, respiration became shallow, and ten minutes later he quietly died.

The autopsy was held eight hours after death, by Dr. J. West Roosevelt, curator to the hospital. No aneurism was found, though there was general vascular dilatation in the neighborhood of the heart; the latter organ weighed, free of clots, *thirty-two ounces;* there was general dilatation, the walls being of about normal thickness. The aortic valve was stenosed, thickened, and insufficient, one cusp being entirely gone. The right auricle lay against the chest-wall to the right of the sternum, behind the first, second, and third ribs. The mitral valve was thickened, but seemed sufficient, as did also the valves of the right heart. The liver was hard, firm, and congested, the upper part of the right lobe showing a distinct depression where the heart had rested. The kidneys were firm, of normal size; cortex somewhat thinned; markings distinct; capsule not adherent; chronic congestion. Both lungs were in a state of pigment induration. The other points of the autopsy call for no special remark.

A consideration of the physical condition and situation of the heart at once accounts for the mistake in diagnosis. The enormously dilated right auricle, lying just behind the ribs, gave the percussion dulness, and through its contents received the direct transmission of the general impulse occasioned by every systole of this veritable "cor bovinum." To the eye, ear, and finger the sensations were those of a true aneurismal sac. Cases of this nature are unusual, at least to such a degree as was manifested here. The weight of the heart is by far the largest which the pathological records of this hospital show.

NEW YORK HOSPITAL.

Report of the Case of Yellow Fever in New York.

By FRANCIS M. DWIGHT, M.D.,

HOUSE PHYSICIAN.

No history of the case was obtainable previous to admission at 10.30 P.M., August 29th, when temperature was 100.2°; respiration, 30; pulse, 100, weak and irregular. The patient was well nourished, and there was no œdema. The skin was intensely jaundiced. The conjunctivæ were injected. The pupils were slightly contracted. There was marked nystagmus, general cutaneous hyperæsthesia, and exaggerated reflexes.

Physical examination showed slight dulness over both chests posteriorly. Respiration in places was tubular and accompanied with fine moist râles. Voice could not be obtained. Cardiac sounds were inaudible. Palpation over the abdomen irritated the patient very much, and apparently caused pain. Examination of the urine showed its specific gravity to be 1,018, acid in reaction, dark yellow in color, with about ten per cent. by volume of albumen.

Digitalis was administered hypodermically. Shortly after admission the patient had projectile vomiting. The vomited matter was very abundant; was entirely fluid, and of the color of claret. Microscopic examination showed it to contain immense numbers of partly decomposed blood-cells, free nuclei, and epithelial detritus.

The patient did not respond at all to stimulation. During the night he was restless and irritable, vomiting at intervals of two or three hours. At 3 A.M., temperature was 101.6° F.; respiration, 24; pulse, 100. Two hours later the patient died. The temperature taken immediately after death was 105°.

The autopsy was conducted by Dr. George L. Peabody, and gave the following results: Body was well nourished, deeply jaundiced, and rigor mortis was well marked. There was no œdema. The brain and membranes were normal. The peritoneal cavity contained no fluid; there was no peritonitis. The diaphragm was normal. There were no pleural adhesions. The heart was normal in size, and bright yellow in color. The endocardium and aorta were deeply jaundiced. The valves were competent. The muscular tissue was pale, yellow, soft, friable, and contained an abundance of fat. The lungs contained countless hemorrhages, varying in size from that of a small pea to a small chestnut, and occurring all through the parenchyma. The lungs elsewhere were intensely congested and œdematous. The spleen was about three or four times the size of a normal spleen, was dark in color and somewhat soft. The kidneys were normal in size and very yellow. The capsules were not adherent, the surface was smooth, and the markings distinct. The cortex was somewhat swollen.

The stomach contained nearly a pint of fluid, which was largely composed of dark-colored blood. The mucous membrane was congested and covered with mucus. Near the pylorus there was some thickening of the mucous membrane. There was no ulceration. The duodenum and upper part of the jejunum were congested and the mucous membrane somewhat swollen. The common bile-duct was pervious. The intestines throughout contained a large amount of blood, some of which was fluid and some thick, dark, and tarry in color and consistence. No ulcers were found. The liver was normal in size. The cut surface was mottled and presented areas, apparently peripheral, of brilliant red color with pale yellowish centres of acini which were deeply jaundiced and contained fat. The gall-bladder contained a small amount of dark thick bile.

Microscopic Examination.—Heart: Abundance of fat was found, both in the form of granules and of small drops, and to such an extent in many places as to obscure the transverse striæ. Kidneys: There was an abundance of granular fat and drops of fat in the epithelium of the straight and convoluted tubes. Elsewhere the epithelium appeared swollen and clouded. Liver: There was much extravasated blood and imbibition of blood coloring matter in the peripheries of the acini; at the centres the cells contained an abundance of fat.

Progress of Medical Science.

Cachectic Purpura.—According to the opinion of Dr. A. Mathieu, purpura hemorrhagica is not a disease sui generis, but is merely a symptom of some other morbid condition. He proposes, therefore, to group together all the various forms of the affection under the general name of *purpura cachectica*, of which he recognizes three groups. The first comprises the various forms of hemorrhage occurring in pernicious anæmia. In the second group the purpura appears in the subjects of tuberculosis. The nervous system plays here an important rôle, so that the affection has been called by some *purpura neuropathica* or *myelopathica*. The hemorrhages occurring in the third division are occasioned by the cachexia of Bright's disease. They are a symptom as frequently met with as œdema. A special form of cachectic purpura, and one which is closely allied to that of Bright's disease, is senile purpura. Atheroma of the arteries is a very important factor in the etiology of this variety. This form of purpura is characterized by its long duration, its peculiar seat, occurring as it does often on the dorsal surfaces of the hands and feet, and on the ulnar side of the forearm, and by the shape of the petechiæ which are small, lenticular, and without any areola. It is also worthy of note that the red globules in this form of purpura, as was demonstrated by Hayem, are normal in function and possess the proper amount of hæmoglobin. The author sums up the results of his investigations as follows: 1. Cachectic purpura appears in the form of petechiæ and of ecchymoses; the first are either pilo-sebaceous or cutaneous, the latter may be very extensive in area. The papular and erythematous forms are never seen in this variety of purpura. 2. The first group, that of excessive anæmia, is characterized by the frequency of œdema and hemorrhage. In this group may be included purpura of the cancerous cachexia and of the anæmia of miners. 3. In tuberculosis the purpuric eruption is caused by the secondary affections, such as meningitis, albuminuria, diseases of the liver, etc. 4. Purpura is a very frequent phenomenon in Bright's disease, and is to be regarded as of evil prognostic import, as it is generally the forerunner of uræmia and death. 5. In the cachexia of heart disease purpura may be induced by a variety of causes, such as albuminuria, pernicious jaundice, arterial sclerosis, œdema, and embolism.—*Schmidt's Jahrbücher*, May 20, 1884.

The Value as a Symptom of the Swashing Sound in the Stomach.—Chomel regarded this sound as a characteristic sign of a morbid condition which he called indigestion of fluids. He believed that the stomach was incapable of absorbing or of passing into the duodenum the ingested liquids or those secreted within the organ itself. These liquids accordingly accumulated within the stomach, and their presence was manifested by a succussion sound on shaking the patient. He considered this sound to be always a pathological phenomenon. These views were controverted by M. Andhoui in a note presented to the Paris Academy of Science (*L'Union Médicale*, July 12, 1884). He had made a number of experiments upon dyspeptic and healthy individuals, and had found the succussion sound always present immediately after the ingestion of a quantity of fluid. He concluded, therefore, that Chomel was wrong in believing it to be a pathognomonic sign of indigestion of fluids, or of any other gastric disorder.

Polyuria in Convalescence from Typhoid Fever.—The attention of Dr. Spitz having been attracted by the case of a convalescent from typhoid fever, who passed from three to four quarts of urine a day, he was led to study the subject more closely. He found, to his great astonishment, that polyuria, sometimes to a remarkable degree, was present in about half the cases of convalescence from typhoid. The amount of urine excreted was usually greater as the fever itself had been more severe. The urine is of a light yellow color, transparent, without sugar or albumen, and forming no special deposit. Its specific gravity varies inversely to the total amount excreted during the twenty-four hours. The polyuria begins at the period of greatest oscillations of temperature and persists up to the fifth or sixth week of convalescence. It would seem to be of favorable prognostic import.—*L'Union Médicale*, July 6, 1884.

Hypodermic Injections of Quinine in the Differentiation of Malarial from Typhoid Fever.—Dr. Annibale Arzelà employs quinine subcutaneously in doses of fifteen grains and more, according to the age and constitution of the patient, as a means of diagnosis between remittent and typhoid fever. If the disease be malarial in origin, soon after the injection a noticeable depression occurs in the temperature curve, which eventuates the next day, perhaps after another dose of quinine, in complete apyrexia. If the affection be typhoid fever the fall in temperature is merely temporary. It is necessary to give the quinine subcutaneously, as the intestinal mucous membrane is in such a condition that absorption of remedies administered per orem may not occur.—*Deutsche Medicinal-Zeitung*, vol. v., No. 50, 1884.

Treatment of Fractured Patella.—Dr. Van der Meulen notes that in the space between the two fragments of a broken patella, a clot of blood is formed. This clot is not organized at once in its entirety, but the anterior and posterior surfaces are first organized, and only after some time does the process involve the central portion. In this way the two fragments come to be united by two thin pseudo-membranes. The author takes advantage of this in his treatment of fractured patella. From ten to twenty days after the injury he proceeds to operate. An incision being made over the patella, the anterior membrane and the unorganized coagulum lying beneath it are removed, but the posterior membrane is not interfered with, and thus the joint is not opened. The fragments are then united by platinum or silver wire suture, care being taken not to include the membrane of organized coagulum, but to let it fold upon itself posteriorly toward the joint cavity. Dr. Van der Meulen has operated in this manner in three cases of fractured patella, and has been enabled to obtain excellent and firm union.—*Deutsche Medicinal-Zeitung*, July 21, 1884.

The Diagnosis of Sciatica.—M. de Beurmann advises, in any case where there is a question of diagnosis between sciatica and any other painful affection in the region of the hip, that the patient be placed on the back and then, the knee being held in complete extension, flexion be made of the thigh upon the trunk. When this is done, the patient at once complains of severe pain in the buttock at the point corresponding to the sciatic notch. If now the knee be flexed, no pain is experienced upon flexion of the hip. According to Lasègue this pain is caused by compression of the nerve by the surrounding muscles, but De Beurmann shows that it is due rather to stretching of the nerve trunk by the constrained position of the limb. This sign, more valuable than that of Valleix's tender points, is, the writer states, constantly present. It is moreover characteristic, for in other affections simulating sciatica the presence or absence of pain is not dependent upon the tension or relaxation of the nerve, consequent upon the varying positions of flexion and extension of the knee.—*La France Médicale*, August 2, 1884.

Treatment of Locomotor Ataxia.—Dr. Müller claims to have had a measure of success in his treatment of this affection. The diet, he says, should be strengthening. Coffee, strong tea, and undiluted alcoholic beverages are forbidden. In the medicinal treatment a pill is used composed of $\frac{1.5}{100}$ grain of nitrate of silver and $1\frac{1}{2}$ grain of extract of ergot. The dose is one pill three times a day, and is gradually increased to three pills three times a day. After about twenty grains of nitrate of silver have been taken, the pills are discontinued for three weeks, when their administration is then resumed in the same way. The treatment may extend over five or six months. The author does not believe that the disease is often of syphilitic origin, and never uses specific treatment unless he can discover unmistakable evidences of syphilis. Electricity is often useful, but galvanization of the medulla should be practised as well as that of the cord. Faradization of the skin by means of the brush electrode, either alone or combined with galvanization of the nervous centres, may also be of advantage. The author condemns hot water or vapor baths as being positively injurious. Cold baths are also contra-indicated. The proper temperature for a bath is 84° to 86°, and the patient should remain in the water for from three to five minutes only. Massage may prove to be of use, though data on this point are wanting. Stretching of the longer nerve-trunks is a dangerous and unwarranted procedure. For the pains Dr. Müller makes local applications of a liniment consisting of veratria, four grains; chloroform, half an ounce; and oil, one ounce. For the gastralgic crises he uses strong faradization with a brush over the epigastrium. Ocular paralysis is treated by the continued current. For the relief of vesical spasm, he gives pills containing one and a half grain of the extract of cannabis indica.—*La France Médicale*, July 31, 1884.

The Weight of the Heart in Cancerous Affections of the Uterus.—It has been stated by Dr. Artaud that the heart is hypertrophied in cases of carcinoma of the uterus, in consequence of secondary inflammation of the kidneys. In a series of post-mortem observations made to verify this assertion (*Le Progrès Médical*, August 2, 1884), Drs. Féré and Quermonne found that such was not the case. As the result of their investigations they conclude that, not only is hypertrophy of the heart not the rule in those suffering from renal lesions consequent upon cancer of the uterus, but that on the contrary, the heart, as is usually the case in cancerous subjects, whatever the seat of the lesion, is more or less atrophied.

A Case of Acute Iodism.—A gentleman in perfect health took a dose of fifteen grains of iodide of potassium in the hope of overcoming the disgust felt for it by his wife, for whom the drug had been prescribed. This occurred about six o'clock in the evening, and no evil effects were experienced until eleven o'clock, after he had retired. He was then suddenly awakened by violent sneezing accompanied by excruciating pain in the upper jaw. This was so severe as to drive the patient nearly frantic. The upper part of the face was somewhat swollen, and nasal respiration was impeded, though there was no discharge from the nostrils. The eyes were suffused without there being an actual flow of tears. There was also some nausea and vomiting. M. Léger, who was summoned about four o'clock, found the patient still suffering from constant pain, with exacerbations every few minutes, in the upper jaw and the teeth. This pain was not increased by pressure upon the infra-orbital nerves. The symptoms pointed to inflammation of the mucous membrane lining the two antra, but no cause could be found to account for its sudden onset, until the patient mentioned casually that he had taken a dose of his wife's medicine. The symptoms continued with but slight abatement until the following evening, and then slowly disappeared, leaving no sequelæ.—*Journal de Médecine et de Chirurgie Pratiques*, July, 1884.

Borax in the Treatment of Contagious Diseases.—In a communication made to the Académie des Sciences (*L'Union Médicale*, August 2, 1884), Dr. de Cyon urges upon the members the employment of borax as an internal disinfectant. It is, he asserts, perfectly innocuous to the human organism, even when taken in quantities of half an ounce or more per diem. He opposes the notion that a microbicide is the more effectual in proportion as it is the more poisonous to man. The efficacy of this substance as a prophylactic against cholera was demonstrated, the author says, during the cholera epidemic which ravaged Italy in 1865. At that time not one of the workmen employed in the seven boracic acid factories at Larderello was attacked, while in a village scarcely two miles distant one-third of the inhabitants died from cholera. Taken in quantities of seventy-five to ninety grains per diem, the borax would not only exert a direct action upon the microbes in the intestinal canal, but would be taken into the blood and destroy the organisms there present. The constipating effect of borax would be another indication as regards cholera. He recommends that those exposed to cholera should wash the mucous membranes frequently with a solution of boracic acid or borax, and also take about ninety grains of borax internally each day.

The Induced Current in the Treatment of Pleuritic Effusions.—Dr. Giuseppe Manzini has collected a number of cases of absorption of the fluid in chronic pleurisy after the persevering use of the induced current applied to the thoracic wall. In a few instances there was at first a little fever and a slight degree of inflammation, induced apparently by irritation from the electricity. Although these cases also terminated favorably, the author advises that the treatment be not undertaken until every trace of inflammatory action has subsided. The action of electricity in causing absorption is explained: 1, by the increased power of contraction in the intercostal muscles and diaphragm, previously weakened by the hyperæmia and œdema, which contraction exerts a pressure upon the fluid contained in the thoracic cavity; 2, by strong irritation of the vasomotor nerves, which restores to the tissues their absorbing power.—*Deutsche Medicinal-Zeitung*, July 10, 1884.

Malaria and Osteopathies.—Dr. Barberi-Boughini, in an article on this subject, notes the anatomical and physiological relations between the spleen and the medullary substance of the bones, and concludes that it is reasonable to suppose that when the former is affected by the malarial infection the latter is also involved. He calls attention to the frequency of non-union or slow union of fractures in malarious subjects, and mentions several instances in which he found melanotic disease of the medulla of one or more of the long bones in cases of hypertrophied spleen from malaria. He concludes that: 1. We should recognize the existence of leucocythæmia due to changes in the various bones. 2. The malarial poison may act by itself in inducing these changes, or may be a most powerful coefficient to the expression of other diatheses not yet determined. 3. Malaria ought therefore to be regarded as a cause of various osteopathies.—*Rivista Clinica*, July, 1884.

The Condition of the Blood in Hydrophobia.—In an examination of the blood drawn rapidly from the vessels, especially from the sinuses of the dura mater, Dr. Romiti (*Rivista Clinica*, July, 1884) found it to be of a dark red color and not coagulable spontaneously. The red globules were rather pale, and when the preparation was stained by Bizzozero's method, and placed under an immersion lens, there appeared a mass of granular matter in which the white globules seemed to be imbedded. These appearances were similar to those presented by the blood of persons killed by snake bites.

The Functions of the Thyroid Gland.—In an article in the *Archivio per le Scienze Mediche*, vol. viii., No. 10, 1884, Drs. Sanquirico and Canalis describe a number of experiments made by them to determine the function of the thyroid gland and its value to the economy. From the results of these experiments the authors draw the following deductions: 1. The extirpation of the entire thyroid gland in dogs is fatal, whether the spleen have previously been removed or not. 2. Dogs from whom the spleen has been taken away bear incomplete thyroidectomy without any apparent ill effects. 3. There is no functional relationship between the thyroid gland and the spleen. 4. Only a small portion of the thyroid requires to be spared in order that the functions proper to this gland may be actively performed and that there may be no change in the animal's general condition; though not yet positively determined, it would appear that the upper part of the gland is the part that must be spared in order not to interfere with its necessary functions. 5. The fatal results following complete thyroidectomy cannot be referred to quantitative changes in the elements of the blood, for the changes observed were neither constant nor of sufficient gravity. 6. Although the experiments thus far made have not demonstrated what the functions of this gland are, they are yet sufficient to exclude the notion of a hæmatogenetic action, and therefore to prove that the thyroid cannot, in this respect at least, be a substitute for the spleen. Nevertheless we are justified in assuming that it has an important action upon the animal, and in all probability in relation with the nervous centres. The authors have never met with an absence of the thyroid gland in any of the animals examined by them, although Tauber has asserted that the organ is quite frequently wanting in the domestic animals.

Sub-clavicular Tympanic Resonance in Pneumonia.—In a soldier suffering from acute double pneumonia, Dr. Lavéran (*L'Union Médicale*, No. 55, 1884) found a tympanic resonance under the left clavicle. This resonance persisted from the third day of the disease until the patient's death. At the autopsy the left lung was found to be throughout in a state of gray hepatization. Not being able in this case to admit the theory of Skoda and others, who explain this phenomenon by the integrity of the corresponding portion of the other lung, Dr. Lavéran concluded that the resonance was that of the trachea and larger bronchi transmitted through the solidified lung-tissue.

Purulent Conjunctivitis.—In a considerable number of cases of purulent ophthalmia Dr. Johan Widmark (*Hygiea*, No. 6, 1884) was able to demonstrate the presence of gonococci. The micro-organisms were generally found in the wandering cells, though they were also present in the secretion. In some cases of conjunctivitis of the new-born the author discovered the cocci in the epithelial cells. In one case also of ophthalmia in the adult they were present in the epithelial cells in the first days of the disease, but disappeared on the third day. The author concludes from this that, as is asserted by Welander to be the case in gonorrhœa, the gonococci are developed in the epithelium, and only later penetrate into the subjacent tissues. In every case Dr. Widmark was able to prove contagion, in adults, from the presence of the gonococci in the antecedent urethral discharge, and in the new-born from the presence of these organisms in the vaginal secretions of the mother. The results of treatment in the new-born were excellent, but the disease in the adult was very intractable. This difference the author explains by the statement that in the adult there is a layer of adenoid tissue beneath the conjunctiva which is wanting in the infant. The micro-organisms have a predilection for all glandular structures, and therefore pass deeply down into this subconjunctival layer out of the reach of local applications. In the treatment Dr. Widmark makes a strong application of nitrate of silver once a day, and washes the eye frequently with solutions of boracic acid and of corrosive sublimate ($\frac{1}{10000}$) employed alternately.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 6, 1884.

CHOLERA AND THE COMMA-BACILLUS.

A VERY interesting lecture on cholera, an abstract of which is given in this and the preceding issue of THE RECORD, was delivered recently by Dr. Koch before an assembly of prominent physicians and hygienists in Berlin. The speaker described the minute organism discovered by him in the intestinal discharges of cholera patients, and which he maintains is the actual cause and essence of the disease. This organism has been called rather inaptly the comma-bacillus, although it resembles a mark of parenthesis more than it does a comma, and is probably a spirillum and not a bacillus. Dr. Koch makes out a very strong point in favor of the bacillus theory of cholera and of his claim to have discovered the special micro-organism that causes the disease. He found the comma-bacillus in every one of nearly a hundred cases of Asiatic cholera, while its presence could not be detected in cases of cholera morbus and other diseases in which a search was made. Nevertheless it would be rash to assert that it is not present in any other disease, and it may yet be found in other affections, just as Friedländer's pneumonic cocci are said to have been detected in inflamed tissues other than the lungs. Indeed, Dr. Klein, a London physician, has recently asserted that he found micro-organisms, indistinguishable from the comma-bacilli, in the discharges of patients suffering from a diarrhœa which was epidemic in Cornwall in 1883. As he made no culture tests, however, his statements cannot be accepted as conclusive. And more than this, the crucial test of a theory of this kind is wanting, namely, inoculation by the infectious material. Various attempts have been made to induce cholera in the lower animals by feeding them with matters containing the comma-bacilli, but always without success. Koch says that animals enjoy a special immunity against the disease; but while this may be a sufficient explanation of the failure of these experiments, it nevertheless leaves the main question of inoculability untouched.

Although it would be premature without further evidence to regard the problem of the cause of cholera as already solved, the possibility of Koch's solution being the correct one is nevertheless so great that it may not be unprofitable to consider some of the sanitary bearings of his theory.

The lecturer stated that the bacillus was found only in the intestinal canal and its contents, and never in any of the other organs or secretions of the body. Further than this, it was only in the lower portion of the digestive canal, the gastric secretion, when normal in character, being fatal to the life of the micro-organism. This point is of considerable importance, since, as the bacillus can gain admission only through the mouth, it must first run the gauntlet of the stomach before it can reach a locality favorable to its development. Thus, a healthy individual whose gastric secretions are normal in quantity and quality, is far less likely to contract the disease than is a dyspeptic. This might explain the influence of fear as a predisposing cause of cholera, since good digestion is so dependent upon a quiet mind. Hydrochloric acid and pepsine may yet rank high among the preventives of cholera.

A still more important statement was that the bacillus is absolutely dependent upon moisture for its life. There is no stage of its existence during which it may remain dormant for an indefinite time, ready for further development and reproduction under favoring circumstances. Once the material in which it is contained be thoroughly dried, then the comma-bacillus is dead and can never be resuscitated.

If this be so, the question of disinfection becomes a very simple one. All rags, clothing, or personal effects of cholera patients need but to be carefully dried, and they are thenceforth absolutely incapable of carrying contagion. In the same way letters could be dried, and the absurd precaution of enclosing them in tarred mail-bags might then be abandoned. The assertion that the infectious material of cholera cannot be carried in the air, but can only be transmitted to distant places by persons suffering from the disease or by articles soiled with choleraic discharges, will, if true, lend a measure of support to the establishment of sanitary cordons, and demonstrate the utility of quarantine. That the bacillus can flourish under favoring conditions outside of the human body, is amply demonstrated by the facts of cultivation in gelatine, milk, blood serum, potato, and other substances. Impure drinking-water would seem to be one of the most ordinary channels through which the contagion of cholera is introduced into the intestinal tract. Dr. Koch cited numerous striking cases showing the value of pure water in reducing the death-rate from this disease. He stated also that the comma-bacillus did not thrive in pure water, but died within a few days.

One of the most valuable results of the discovery of the cholera bacillus, even though it be proven not to be the real cause of the disease, provided only that it be peculiar to this affection and not present in any other, will be the facility thus afforded to a certain and early diagnosis. The value of this can hardly be over-estimated, for the first cases usually come singly, and if they can be promptly recognized and placed under surveillance from the very beginning, a destructive epidemic may be warded off. Whereas, if the first few days be spent in trying to decide what the nature of the disease is, by the time it is recognized to be cholera it may be too late to check its advance. Dr. Koch maintains that a simple microscopical examination of the choleraic discharges is not always sufficient to base a diagnosis upon, but that by the method of culture absolute certainty may be obtained. He looks upon this as a very simple matter, and seems to think that anybody can do it. But he appears to be a

little over-sanguine in this respect. It is hardly reasonable to expect that every physician will take the trouble, even if he has the time to spare, to acquire the skill necessary for conducting a trustworthy culture of the comma-bacillus. But practically, in cities at least, such a general knowledge of bacteriology is not necessary. The investigation of doubtful cases could be entrusted to the sanitary authorities, as is done now in other contagious diseases.

It is to be hoped that Koch will be able to substantiate his claims clearly and beyond dispute, for we shall then be on the high road to victory over this dreaded disease, and cholera will take its place alongside of small-pox as one of the former scourges of the human race from which modern civilization has little to fear.

GASTRIC HYSTERIA, AND THE FASTING GIRL OF FORT PLAIN.

The necessity of a suitable dietary regimen is seen in the fact that man, and warm-blooded animals generally, cannot survive abstinence from food longer than from seven to ten days; the period may be somewhat extended if water be supplied, and it may be very much prolonged if a minute quantity of nutriment be taken daily.

Cold-blooded animals can endure fasting for a considerably longer time; although some species (notably of fishes) are characterized by excessive voracity, and all are dependent for the normal performance of their functions on regular alimentation, it is nevertheless a fact that reptiles and amphibia have been known to live for many months without any food whatever. A gentleman, for whose veracity we can vouch, has reported to The Record a case of nine months' fasting in a couple of frogs;[1] and an alligator now in our possession has for more than ninety days refused all sustenance. Such warm-blooded animals as hibernate during the cold season are examples of a similar kind. In all these instances changed conditions in the environment have caused retardation—a quasi stagnation of the organic processes; assimilation and disassimilation are almost nil; animal heat is scarcely above that of the surrounding medium; secretion and excretion are at their minimum.

Although all active manifestations of life are the expression of change in the protoplasmi matter of life, necessitating constant waste and repair, yet there are all grades of vital action (and concomitant molecular change); from the "latent life" of spores and seeds and grains, of dried rotifers and tardigrades and certain infusoria, which are capable of existing for years in a state of physical and chemical torpor without maintaining any relations of exchange with their environment; to the instances already given of "life with oscillations" (the terms are those of M. Claude Bernard), where the condition is not one of absolute torpor and inertness, but one in which the vital manifestations are at a low ebb; to finally—what shall we take as our highest example?—to the indefatigable activity which characterizes that hardest-worked of human beings, a metropolitan newspaper editor.

There are in man certain morbid conditions which almost reduce the individual to the state of a cold-blooded or hibernating animal, as far as the ability to support deprivation of nutriment is concerned. Not to dwell on certain cases of cancerous stricture of the pylorus or cardia, where digestion and absorption are almost, if not quite, impossible, and yet where we have seen life maintained for many long weeks on the *nutritive reserves*[1] of the blood and tissues; there are certain cases of hysteria characterized by chronic repugnance to and inability to digest food; these cases are called by Huchard and Denian "gastric hysteria."[2]

We here say in advance that the intimate nature of this disease is still unknown to science. Protean as are the manifestations, we have not yet ascertained the nexus of its parts or the law of its unity. Believing, as we must do, that it has a definite patho-anatomical basis, we are forced to conclude that the morbid alterations are principally molecular, being a disturbance of interstitial processes of waste and repair. We are warranted in affirming that in gastric hysteria there is marked inhibition of those systemic processes through perverted nervous influence, the point of departure being a local irritation which, to the functions of organic life, becomes a paralyzing lesion.

In gastric hysteria either the appetite remains normal or nearly so, but food is vomited shortly after it is ingested, from atony of the digestive organs, and failure of the assimilative processes; or else the appetite is completely lost, while organic nutrition is at a stand-still; the aversion to food is invincible. In the former class of cases abstinence is in some sort instinctive, the patient dreading the distress and vomiting which follow eating. In the latter class there is also retardation of the processes of vegetative life, but there is a mental element which is conspicuous; as though the dread and disgust of food were a species of insanity, having a special seat in the brain. Huchard distinguishes these two varieties under the names of *gastric anorexia* and *mental anorexia*.[3] The mental anorexia of Huchard has been described by Gull, of England, under the name of *hysterical apepsia*; "an affection chiefly seen in young girls from fifteen to twenty-three years of age, and characterized by complete loss of appetite, by emaciation often attributed to latent tuberculosis, abdominal disease, or tabes mesenterica, and due especially to central cerebral disturbance."[4]

Other cases of gastric hysteria are distinguished by incoercible vomiting, which may be due to hyperæsthesia of the gastric mucous membrane, to pneumo-gastralgia, to secretory disturbances of the gastric glands, and to other causes.

All the neuralgic, spasmodic, paralytic, and other nervous troubles of hysteria in general, may accompany this form of hysteria, and be the key and the exponent of the malady. To cite one of multitudes of illustrative observations on record, we may refer to the very interesting case reported by Raymond in Vulpian's "Clinique Médicale," obs. clvi.[5] The patient was suffer-

[5] Clinique Médicale de l'Hôpital de la Charité. Obs. Cliniques par le doct. F. Raymond. O. Doin, Paris, 1879.

ing from "ovarian hysteria;" entered the hospital to be treated for incomplete paraplegia which proved to be reflex; while in La Charité had gastric hysteria, vomiting everything; this was accompanied by choreiform trembling of the limbs, which lasted for several months; both the choreic agitation and the vomiting were very obstinate; there was sometimes alternancy of the morbid phenomena, one kind being in abeyance while there was exacerbation of another kind. The patient left the hospital unrelieved.

As for the length of time during which life may be maintained on such limited quantities of food as are assimilated in these cases, it is impossible to form an exact estimate. Dr. Carpenter relates an instance which came under his own observation: "A young lady who had just before suffered severely from the tetanic form of hysteria, was unable to take food for three weeks. The slightest attempt to introduce a morsel of solid matter into the stomach occasioned violent efforts at vomiting; and the only nourishment taken during the period mentioned was a cup of tea once or twice a day, and on many days not even this was swallowed. Yet the strength of the patient rather increased than diminished during this period; her muscles became firmer and her voice more powerful."[1]

Willen relates the case of a man who lived sixty days without taking anything but a little orange juice. Desbarreaux reports the history of a woman who during sixty-one days swallowed only one bowl of broth. And Desportes tells of a woman who during two months lived on water alone. Denian, from whom we borrow these not very well attested statements, after remarking the slowness of disassimilation in gastric hysteria, of which we have a proof in the minute quantity of urea which is excreted (in some instances scarcely thirty grains a day), goes on to observe that "alienists are every day witnesses of facts of persisted anorexia and abstinence supported with an immunity truly astonishing."[2]

The disposition to deceive which characterizes hysterical patients generally is not absent from the gastric form of the disease, and the cases of Anna Moore, Sarah Jacobs, etc., reported by Dr. Hammond in his "Fasting Girls," show us to what bizarre subterfuges these patients will resort to impose upon family and friends, and compel the belief that absolutely no nourishment of any kind is ingested.

A notable instance of simulated fasting, which had a tragic ending, occurred in South Wales in the spring of 1869 (*vide* newspapers of that period, heading "Fasting Girl of South Wales"). The parents made a show of their child, decking her out like a bride on a bed and asserting that she had eaten no food for two years. Some reckless enthusiasts for truth set four trustworthy hospital nurses to watch her; the Celtic obstinacy of the parents was aroused, and in defence of their imposture (or because they had allowed themselves to be deceived) permitted death to take place in eight days. Their trial and conviction for manslaughter are still fresh in the memories of inhabitants of that region.[3]

Whether the same result would follow a rigorous espionage, day and night, of the person and surroundings of the fasting girl at Fort Plain, is not in our mind at all uncertain. It would appear that Miss Kate Smusley has now been for almost six months "lying at death's door from self-starvation." She occasionally "takes a little water in her mouth, but does not swallow it, as this causes convulsions which wrench her stomach most painfully. . . . She recognizes her callers, and carries on conversations with them, and is perfectly conscious. . . . Her body is in constant motion, like a machine, so much so that the bed upon which she lies has to be supported for fear that it will fall to pieces by the constant vibration." Other non-medical accounts of a similar kind, based on asseverations of members of the family, are in circulation. We have a medical opinion of the case from the statement of a local physician whose name we charitably suppress, and who considers the case "one of spinal disintegration, or a species of locomotor ataxy, or a wasting of the nervous system!"

It is needless to comment on such an extraordinary view of a case which, as far as we have been able to inform ourselves concerning it, is clearly an instance of gastric hysteria, and presenting no single element that is essentially different from other cases of the kind, unless it be the persistent choreic trepidation, which seems to be a more obstinate and formidable phenomenon than in Vulpian's patient above referred to. There would seem to be a tetanic condition of the œsophageal muscles at times, making swallowing an impossibility. We can well believe that Miss Kate Smusley is a great sufferer and entitled to universal pity; that, however, there is fraud and imposture in the recital, as it comes to us, there can be no doubt whatever.

INTRAVESICAL INJECTIONS.

Of the many therapeutic measures in common use for the alleviation or cure of vesical troubles, few have such power for good, when rightly used, or such injurious effects when misapplied, as injections into the bladder. *J'en pense beaucoup de bien et beaucoup de mal*, said Guion, when questioned as to their value. Like most of the therapeutic means in the hands of the surgeon, whose value cannot be questioned, they are two-edged weapons—excellent, harmless, and productive of good results in experienced hands, but dangerous when entrusted to the inexperienced and ignorant. Hæmaturia, prostatitis, cystitis, and even nephritis are the troubles arising from misuse of them, troubles depending upon the *technique* of the injection, its nature, and its pharmaceutical composition.

Intravesical injections may be used in the most diverse conditions, and to obtain essentially different results; for a simple mechanical action, or for a modifying dynamic action on the bladder or its contents, or as very necessary aids in certain operations upon the bladder.

Evacuating injections or washes may prove valuable mechanical aids by acting mechanically on foreign substances in the bladder, and causing their expulsion. The substances to be removed may be gravels or fragments of calculi, or purulent or glairy masses which, on account of their weight or adhesive power, cannot be

expelled by the forces of micturition. It is well known that in cases of pyluria, the last urine expelled contains more pus than the first, often consisting of almost pure pus; and the unexpelled contents consist of pus, or at least urine mixed with pus, which stagnates in the bladder. Now, there is scarcely a surgical principle more universally admitted than that every suppurating surface should be placed under conditions favorable for cleanliness and drainage. This is the underlying principle of detersive vesical injections, which are indicated whenever the urine contains pus, and especially when the pus is secreted by the vesical mucous membrane. So, also, when the urine undergoes ammoniacal fermentation, or there are solid blood-clots in the bladder.

As with other measures which are powerful for good, vesical injections have their contra-indications, of which pain may be mentioned first. The injection should not cause any considerable degree of pain, nor should the bladder be distended by the fluid. After pain, acute renal lesions contra-indicate detersive injections. We do not say chronic lesions of the kidneys, because in that case they would be almost entirely thrown out of vesical therapeutics.

It would scarcely be considered necessary to say that metallic catheters should never be used for this purpose, unless we had seen it done. Furthermore, Desnos has shown, in his *Lithotritie à Séances Prolongées*, that an evacuating tube should have two eyes, both for lithotrity operations, and for washing out the bladder. The reason for this is apparent: the contents of the bladder should be as much agitated as possible during the injection, and it is easily seen that a tube with two eyes will create a double current, which the single eye cannot. The double-current canula, formerly much used, is decidedly disadvantageous on account of the necessarily small calibre, its inability to set up a double current, and the insignificant attraction at the external orifice. But of all syringes for vesical injections the hydrocele syringe is probably the best. Whatever syringe may be used, however, and however carefully it may be graduated, the amount of liquid thrown in should only be judged of by the resistance of the bladder; and the injection cease at or before the first manifestation of vesical resistance.

As it is always unwise to empty a distended bladder, unless the patient is in the recumbent posture, so vesical injections should always be made while he is lying down. As to the materials for vesical injections, it may be said in a general way that nothing should be used which can possibly do injury, either directly or indirectly. For antiseptic injections solutions of carbolic or boracic acid, resorcine, corrosive sublimate, and strong tea, are all excellent. Nitrate of silver has been much used in this country, and is still used in France; but the less of that material thrown into a bladder, so much the better for the patient.

THE DEVELOPMENT OF CANCER FROM CICATRICES IN THE STOMACH AND GALL-BLADDER.

The question whether cancer may have for its starting point simple ulceration and subsequent cicatrization, has been frequently raised in connection with gastric ulcer. While Rokitansky and Dittrich merely affirm that there are cases in which cancer has followed upon ulceration, Lebert sees in the not infrequent coexistence of gastric ulcer and carcinoma (9 per cent. of his own observations) more than a chance occurrence. And Leube ascribes to the presence of an ulcer or its cicatrix a certain predisposition for the development of cancer. In a monograph on chronic ulcer of the stomach, its cicatrization, and its relationship to cancer, reference to which was made in these columns in September of last year, Dr. Hanser has shown that the glandular changes induced by the cicatricial process occasion a predisposition to cancerous growth, and that between the cancerous growth of the glandular epithelium and its atypical growth in the course of cicatrization there is but a very slight difference. Dr. M. Heitler, of Vienna, agrees with these views, and in confirmation of their correctness cites three cases with autopsies, in which cancer had arisen from the cicatrix following ulceration. This author further states that the same thing may occur in the gall-bladder as in the stomach. In opposition to Frerichs, Förster and others, who regard the presence of a cancerous tumor as favorable to the formation of gall-stones, Klebs and Schüppel regard rather the irritation caused by the presence of biliary calculi as favoring the development of carcinoma. Dr. Heitler is led to agree with the latter by reason of his own experience, which though limited to a single case of this kind, he holds to clearly establish the correctness of the view of Klebs and others. He asks finally whether, with this experience, the appearance of cachexia (especially when there is unhereditary history of cancer) should not be regarded as an indication for operative interference.

THE ASSOCIATIONS FOR THE ADVANCEMENT OF SCIENCE.

The annual meeting of the British Association for the Advancement of Science, at Montreal, last week, and that of the American Association, at Philadelphia, this week, have attracted unusual attention. Both meetings have been interesting, and have fairly served their purpose of giving opportunities for social intercourse and mutual interchange of opinion.

It sometimes occurs that subjects of much interest to medical men come up in the Sections of Biology or Anthropology. Such has not been the case this year, and we much regret the fact. It is noticeable that in both France and Germany there are scientific associations in which the medical sciences form a prominent part. Such is the case with the French Association for the Advancement of Science, and the German Society of Naturalists and Physicians. It would be better if certain of the medical branches were to ally themselves to these associations for the advancement of science. Certainly pharmacology, physiology, pathology, and anatomy are as legitimate and important sciences as any that at present receive attention.

INDIANA MEDICAL AMENITIES.

An interesting controversy is going on between the *Indiana Medical Journal* and a Fort Wayne medical contemporary. The latter publication is opposed to the establishment of a Board of Medical Examiners independent of the colleges, and to the *Indiana Medical Journal*

being made the organ of the State Society. It intimates that those medical gentlemen who are not connected with a medical college are too ignorant to be State examiners—an opinion which has been modestly advanced by learned professors in our own neighborhood. To this the *Indiana Medical Journal* at once applies an *argumentum ad hominem*, quoting from an article by the learned Fort Wayne editor, who, it is needless to say, is a full-fledged professor in a second-rate medical school. It is shown that said professor advises the administration of three grains of quinine and three grains of Dover's powder every three hours as a "bitter tonic" to a child two years old. He also gives this dose in the form of a seven-grain capsule, the whole prescription being written in what might be called dog Latin, and displaying a massive ignorance of therapeutic knowledge and literary skill.

The *Indiana Medical Journal* has been making a good fight for reform in professional education and ethics in the State of Indiana. It is right in its position as to the State Medical Examiners, even if its somewhat personal method of argumentation is not conclusive. Indiana needs a good independent State Board of Medical Examiners much more than it needs any of the literary or educational productions of Fort Wayne.

CONTAGIOUS PLEURO-PNEUMONIA.

Contagious pleuro-pneumonia has already infected several herds in the West, although the total number of its victims is still small, not exceeding fifty. Much to the dismay of the milk-dealers, it has been found to exist in an unequivocal form also in Brooklyn. The disease has been present at several points in the Eastern States for a long time, and there is no doubt that it was carried West from some Eastern herd.

The attempts to throw doubt as to the true nature of the disease, are simply the expressions of obstinacy and dulness. The disease is contagious pleuro-pneumonia—a thing not to be trifled with.

The history of the progress of pleuro-pneumonia in this country of late years has been a curious illustration of the advance of scientific knowledge before public opinion. No competent persons (except a few "inoculationists") doubt that the only way to treat pleuro-pneumonia is to kill every animal that has the disease, and quarantine those that have been exposed. This is the cheapest way in the end, but it has been very hard to show legislators that such is the fact. In the State of New York the Legislature has abandoned its special machinery for dealing with cattle diseases, and there are now only the State and Local Health Boards. The congressional mind has never been able to comprehend the situation, although Congress alone is able to purge the country of the disease.

Pleuro-pneumonia is a most inviting disease for the pathologist to study. It has a special contagion of persistent vitality, but generally of slow development. It produces a local disease wherever it fastens itself, but normally the affected places are the bronchi and air lobules. Here we have a bronchitis, peribronchitis, consolidations, hemorrhagic infarctions, and pleural effusion.

The general features of the disease, however, were described in The Record some time ago and need not be repeated now.

News of the Week.

A Tribute to Marion Sims.—*L'Union Médicale* of August 16th devotes its feuilleton to an account of the life, work, and character of the late Dr. Marion Sims.

Symmetrical at Least.—In Italy cholera attacks the peasants, the peasants attack the doctors, and the doctors attack the cholera. The cholera seems to be coming out ahead, perhaps the peasants come next.

Dr. Oliver Wendell Holmes celebrated his seventy-fifth birthday on August 29th. He received the congratulations personally, by mail, and by telegraph of a large circle of friends and admirers throughout this country and Europe.

Appointments in the Faculty of Medicine of Paris.—M. Lannelongue has been made Professor of External Pathology in the Faculty of Medicine of Paris. M. Armand Gautier has been made Professor of Medical Chemistry in the same faculty.

A New Medical Author.—A contemporary says: "Jahrbuch reports the treatment of forty-three cases of diphtheria with oil of turpentine." Dr. "Jahrbuch" had excellent results. We are reminded of the Freshman who inquired at the library for the works of "Ibid."

The Treatment of Dysentery by Corrosive Sublimate and Colocynth.—Dr. F. Sieber, of Chicago, Ill., writes us, calling attention to the fact that the method of treating dysentery advocated by Dr. S. W. Childs in The Record of August 23d is no new thing, but was described in The Medical Record, vol. xiv., pp. 45 and 194.

The Cholera continues to spread in the Pyrenees villages and has finally reached Madrid, Spain, where it has caused great consternation. It has also extended itself still further through Italy, having infected eleven provinces already. The total number of deaths from cholera up to September 4th is over 5,000. The cholera is now killing about one hundred persons a day, if the telegraphed reports are correct.

The Death of Dr. J. Collis Browne is announced from London. He formerly belonged to the medical staff of the British Army, and devised the well-known preparation "chlorodyne," for the cure of diarrhœa and similar diseases prevalent in the tropical possessions of England. Although the remedy was largely imitated and counterfeited, it is said to have secured great wealth for its inventor.

A Mild Form of Hydrophobia.—There seems to be little doubt that the following curious series of events occurred near Eufaula, Ala. On July 25th a dog on a plantation bit a mule and several hogs; nineteen days later the mule and one of the hogs died with the symptoms of tetanus. Within the next week three more of the bitten hogs died with the same symptoms. The dead hogs were eaten by some thirty negroes, about half of whom were within ten or fifteen days attacked with what Dr. Johnson, the attending physician, calls "a mild form of hydrophobia."

Death of Dr. Robert J. Heinmuller.—We regret to announce the death of Dr. Robert J. Heinmuller, on

August 30th, at his home in this city, of apoplexy. He was twenty-nine years of age, and a graduate of the University Medical College. Since 1881 he had been connected with the Health Department, and held the position of Assistant Sanitary Inspector in the Bureau of Contagious Diseases. He was a member of the County Medical Society, and of the Physicians' Mutual Aid Association. He had been an interne at Bellevue Hospital, and was for a time well known as a quiz master.

Some Dubious Advice Regarding the Cholera.—A French doctor being applied to by his mother-in-law for a receipt to keep off the cholera, recommended the following prophylactic regimen: Sit for a quarter of an hour morning and evening in a strong draught. Drink at each meal a bottle of adulterated wine. Eat two green melons at breakfast, the same number at dinner. Walk in the sun with the head uncovered for an hour every noon. Get yourself into a violent perspiration, then drink a pitcher of ice-water and sit in the cellar in a chemise. Drink ice-water every hour that it is hot. Le culte de Venus matin et soir. If you have any early symptoms of cholera, don't believe it.

The Danger from Chinese Lepers.—Says *The Pacific Medical and Surgical Journal*: "Since the foundation of the State of California, thirty-five years ago, Chinese immigration has gone on, with the introduction of occasional cases of leprosy, and in all those years, comprising more than a third of a century, only one doubtful case of leprosy has been found to prove the risk of the disease extending to the white population. The subject has more than once been considered by the State Board of Health, and not a solitary instance has been reported from any part of the State." It is interesting to compare this statement with the history of leprosy in the Sandwich Islands, where the disease has spread so disastrously.

Home Criticisms of the American Institute of Homœopathy.—The *New York Medical Times* (homœopathic, in a measure) charges the American Institute of Homœopathy with being a machine-ridden and obsolete institution which has outlived its usefulness. It calls upon it to renounce its title or disband, and states what is now very well known, that "homœopathic colleges," "homœopathic publishers," "homœopathic pharmacies," etc., cling to their distinctive name because it is a trade-mark without which they would become extinct. When the leading homœopathic (we beg its pardon) journal of the country talks in this bold way, we opine that the end is near. Homœopathy should be taught in all medical colleges as a branch of historical medicine, or psychological therapeutics. In that direction matters are rapidly tending.

A Case of Yellow Fever was discovered in this city last week. The patient was picked up in an unconscious condition on the street, and no history of his illness could be obtained. From his appearance it seemed probable that he was a sailor. He was taken to the New York Hospital, where he continued semi-comatose, but developed a high temperature. Symptoms of black vomit, yellow skin, and subcutaneous hemorrhage appeared. He died the next morning. Post-mortem examination revealed a yellow, mottled liver, hemorrhage in the stomach and intestines as well as in the lungs, enlarged spleen, and yellow kidneys. The black vomit, the pronounced yellow staining of the skin, and the subsequent discovery of gastro-intestinal and pulmonary hemorrhages justify the diagnosis which was made. For further particulars we refer to the report of Dr. Francis E. Dwight, House-Physician to the New York Hospital, on page 264. Since the occurrence of this case reports of two others in Brooklyn have appeared in the daily papers, but these lack confirmation.

The First Manufacturer of Pepsin.—At the meeting of the American Pharmacological Association at Milwaukee, last week, Mr. Henry Biroth, of Chicago, exhibited several bottles of a preparation called "pepsan," which he believed to be of historical interest. The preparation, he said, was put up in 1853 by one Eben Owen, of Chautauqua County, N. Y. Owen lived the life of a hermit, and was generally spoken of as "Crazy Owen." When he died his cabin was found to contain several packing cases filled with bottles of the preparation which he called "pepsan," and which he had put up himself. Accompanying the stuff were printed circulars quaintly worded as follows:

Pepsan, for the cure of dyspepsia, jaundice, liver complaint, together with all diseases arising from a disorganization of the stomach. This, I believe, is the gastric juices of the stomach of the ox producing the gastric juice required by man to digest his food. Prepared by Eben Owen; by no other, I believe, in this world. Directions for using: Take a small half-teaspoonful fifteen minutes before eating in a half gill of cold water. My advice is to eat light suppers. This is got up under prayer, and will do good I believe. Eben Owen.

April 25.

Mr. Biroth stated that the so-called "pepsan" was what is now known as "pepsin," and intimated that the valuable aid to digestion now known and used by dyspeptics the world over was originally discovered and manufactured by "Crazy Owen."

Veratria in the Treatment of Muscular Tremors.—Dr. Feris has employed veratria in a number of cases of tremor from alcoholism, in convalescence from typhoid fever, and in multiple sclerosis In every case the tremor was quickly overcome, but in the last instance the improvement was only temporary. From his experience in these cases the author formulates the following conclusions: 1. Veratria cures muscular tremor occurring in alcoholism and in certain nervous affections. It will probably cure all forms of tremor, but is especially serviceable in that of alcoholism. 2. The effects of the remedy begin to be manifested within twenty-four hours. 3. In cases in which veratria is of avail it overcomes all tremor, not only of the hands but also of the tongue, lips, etc. 4. The influence of the treatment is prolonged. The author has seen the relief persist for two months. The dose is four pills per diem, each pill containing ½ milligr. (about $\frac{8}{1000}$ grain of veratria).—*Rivista Clinica e Terapeutica*, No. 6, 1884.

Potash Chlorate in Gonorrhœa.—Dr. J. Milton (*Medical Age*, April 25, 1884) states that he has had excellent results from the internal use of the following mixture in ordinary cases of gonorrhœa: Potash chlorate two drachms, boiling water four ounces. Mix and shake till solution is accomplished; then add potass. acetat. two drachms, spirits of juniper four drachms, camphor mixture six ounces. M. S. Dose, a tablespoonful twice daily.

Reports of Societies.

THE INTERNATIONAL MEDICAL CONGRESS.

Eighth Session, held in Copenhagen, Denmark, August 10 to 16, 1884.

General Summary of Proceedings.

(From our Special Correspondent.)

Copenhagen, Denmark, August 18, 1884.

On Saturday, August 16th, the president of the Eighth Session of the International Congress bade adieu to the members, and in a few simple and evidently heartfelt words, closed the series of most successful meetings which have just been held at Copenhagen.

The old French custom, which is expressed by the words, "Le Roi est mort, vive le Roi," was here improved upon. The reigning Congress was not yet dead before its successor was decided upon and proclaimed. After Professor Panum had delivered the closing general address (see page 203),

ON THE INVESTIGATIONS OF FOOD RATIONS FOR MEN IN A STATE OF HEALTH AND DISEASE,

the report of the committee upon the invitation

TO HOLD THE NEXT CONGRESS AT WASHINGTON, IN SEPTEMBER, 1887,

was read, and, as already cabled, adopted.

There were a great number of excellent papers read, and important discussions held in the different sections, the results of which will soon be laid before the medical world.

A VERY LARGE ATTENDANCE.

In a previous letter reference was made to the opening proceedings; but it was not till the meeting was well advanced that a reliable estimate could be formed as to the character and dimensions that the gathering would ultimately assume. No one, and least of all, apparently, those who were organizing the matters here in Copenhagen, had the least idea that the Congress would attract the numbers it had done.

By Wednesday morning, when the sittings of the sections were suspended for

THE EXCURSION TO ELSINORE,

the membership had grown to between sixteen and seventeen hundred, and the number of foreign members who had been attracted to the great Congress of 1881 had been greatly exceeded. This unexpected development, so far as regarded the membership of the Congress, would be sufficient to account for any hitch which might occur in the organizing machinery. Nobody, accordingly, was disposed to be over-querulous by reason of the fact that

THE LODGING CAPACITY OF THE DANISH CAPITAL

was felt to be uncomfortably straitened. The least satisfactory result was seen in the sectional arrangements, which will probably make the preparation of the Congress transactions very difficult, if not impossible, of complete attainment. From the same causes which were at work in this last respect, representatives of the several medical journals found it more than usually difficult to gather up anything like a complete résumé of the sectional proceedings.

SECTIONAL WORK.

For the English-speaking members, however, interest centred most largely in the sections of surgery and medicine; and in the case of these two I shall be enabled to present in The Medical Record sufficiently full and reliable abstracts of the papers and debates.

HOSPITALITIES.

As to the hospitalities and courtesies, these at no time showed signs of break-down. The private hospitalities of the Danish physicians will live long in the recollection of their special recipients. But of the unfailing courtesy, kindliness, and even exuberant hospitality shown to every member of the Congress by the king, profession, and people alike, the memory will only die with the life of each and every member. The king showed from the beginning to the end of the meeting his warm appreciation of the intellectual distinction which its presence conferred on his capital. His presence added lustre to the opening meeting of the Congress, his kindly and generous goodwill gave the members the pleasure, on the Wednesday, of

A VISIT TO ELSINORE,

which will not be readily forgotten, and, on the Friday evening extended to them the honor and enjoyment of a reception and supper at the palace of Christiansborg, at which the king and queen, and all the members of the royal family were present. The dinner given by the municipality on Thursday evening may be described, for want of a better adjective, as also right royal in character; and the popular appreciation of the work of the Congress and its representative men, was completed by the fête given to the members in the Tivoli Gardens on the same evening, and by the farewell feast given on the night of Saturday in the national establishment.

[The scope of the general addresses has been indicated by summaries which have been sent by cable. In two of them—those, namely, of Sir William Gull and of Professor Panum—as already stated, proposals were made for collective investigation. Professor Panum's proposition did not result in any definite action on the part of the Congress. But in the case of

THE COLLECTIVE INVESTIGATION OF DISEASE

a different course was taken and the following committee was appointed: Professors Trier and Lange, of Copenhagen; Drs. Bull, of Christiania; Rauchfuss, of St. Petersburg; Schnitzler, of Vienna; Pribram, of Prague; Bouchard, of Paris; Lepine, of Lyons; Ewald and Bernhardt, of Berlin; Sir William Gull, Professor Humphrey, and Dr. Mahomed, of England; Sir Joseph Fayrer, London (India); Professor Jacobi, of New York; Dr. Davies, of Philadelphia; Dr. Goutteriez Ponce, of Colombia; Professor Despine, of Geneva; and Dr. Isambard Owen, of London, Secretary General.]

As to the work of the sections, it has already been indicated that the section on surgery was the one in which centred the chief interest of the meeting. Here, perhaps, the most important discussion was that which took place on

THE LISTERIAN SYSTEM OF ANTISEPTICS,

and which, while it showed the continued existence of a sincere and general acceptance of the principles underlying antiseptic surgery and admiration for its author, at the same time exhibited an immense variety of opinion and practice as to the methods after which surgeons seek to follow out their principles.

Interesting and important discussions were held on the paper of Mr. MacEwen, of Glasgow, on

OPERATION FOR GENU VALGUM,

this particular debate being remarkable for the almost complete renunciation of their own methods by other surgeons in favor of Mr. MacEwen's; on the paper of Whitson, of Glasgow, on the treatment of club-foot; on a paper of Professor Ollier, of Lyons, on the operation of arthrotomy for tuberculous joint affections; and on the subject of extirpation and other operations for the cure or relief of malignant disease of the rectum, introduced

in a remarkable communication by Professor Esmarch, of Kiel.

In the medical section there was a comparative absence of large debates on subjects of a very general interest, except perhaps in the instance of the questions of

TUBERCULAR PATHOLOGY AND TREATMENT,

and on the

MALARIAL INFECTION IN MAN.

The first-mentioned discussion was noteworthy chiefly on account of the declaration of Professor Jaccoud, of Paris, as to the

ALMOST UTTER STERILITY, FROM A CLINICAL POINT OF VIEW, OF DR. KOCH'S DISCOVERY OF THE BACILLUS TUBERCULOSIS.

Further observations might, he said, be followed by more encouraging results; but so far at least the discovery had borne no fruit in the treatment of the disease.

In the same section some progress was made in the report of Dr. Austin Flint's committee, in regard to the question of the establishment of a

UNIFORM NOMENCLATURE OF AUSCULTATORY SOUNDS IN THE DIAGNOSIS OF DISEASES OF THE CHEST.

The like question of international uniformity of nomenclature came up in the section of gynecology and obstetrics on the report of Professor Simpson's committee; and in this case the section reaffirmed the importance and desirability of the object in view, and reappointed the committee for further consideration of the question and report to the next Congress.

Of the other work in this section that which excited most interest was a prolonged debate on the question of

TREATMENT OF UTERINE FIBROMATA BY LAPAROTOMY,

introduced by a paper by Dr. Koeberle, of Strassburg, and on kindred subjects of abdominal surgery—the debate being taken part in by, among others, Professor Eustache, and Dr. Apostoli, of Paris; Dr. Margary, of Turin; and Sir Spencer Wells, of London.

Of the other sections that of skin diseases perhaps came next in interest. Here again the question that most excited debate was that as to the

TUBERCULOUS CHARACTER OF THE LUPUS.

Professor Kaposi, of Vienna found himself practically alone and unsupported in the negative view of this question, as against Professor Doutrelepont, of Bonn; Dr. Lelair, of Paris; Professor Nierser, of Breslau; and Professor Lang, of Insbruck. Of special interest was a communication by Dr. Goldscheider on the

SPECIFIC SENSIBILITY OF THE SKIN.

Prolonged consideration and discussion of different phases of syphilis was given rise to by a paper by Professor Pick on

EXCISION OF THE INITIAL SCLEROSIS IN SYPHILIS,

and other communications.

Questions as to tubercular conditions cropped up in others of the sections, as in that of pathology and morbid anatomy, the impulse to the discussion being given by a paper of Professor Chauveau, of Lyons, on the

IMPORTANCE TO BE ATTACHED TO TUBERCULOSIS IN DOMESTIC ANIMALS, CONSIDERED AS A SOURCE OF TUBERCULOSIS IN MAN,

and a relative paper by Professor Bang, of Copenhagen.

In the same section Sir William Gull and Professor Cornil, of Paris, read papers on

NEPHRITIS AND ITS SPECIAL TISSUE-CHANGES.

In the section of ophthalmology of special importance was a paper of Professor Holmgren, of Upsala,

ON THE COLOR SENSE;

as to which several new and interesting points were brought forward. Another matter of interest in this section was

THE INFLUENCE OF JEQUIRITY IN GRANULAR CONJUNCTIVITIS AND PANNUS;

and of interest were papers on "Latent Squint," by Drs. Hansen-Grut, of Copenhagen, and Noyes, of New York.

THE SUBJECT OF REFRACTION

was introduced in a paper by Professor Schmidt-Rimpler, of Marburg, who detailed a new method of estimating refraction by means of the ophthalmoscope. The subject was well discussed from a practical point of view by Noyes, Berry, Juler, Sattler, and others.

THE FEATURES OF THE WORK IN THE SECTION OF LARYNGOLOGY

which were of practical interest were found in papers of Dr. F. Lemon, of London, on an "Etiological Classification of Motor Impairments of the Larynx," with a relature by Dr. Cadier, of Paris, on "Paralysis and Pareses of the Larynx."

Dr. Lefferts, of New York, read a very interesting paper on the "Operative Removal of Foreign Bodies from the Air-passages."

Dr. Cohen read a paper on "Prognostic Significance of the Several Local Manifestations Observed in Tuberculosis of the Larynx."

In military medicine, Dr. Schmulewitsch's paper was one of interest; but some subjects put down in this section were discussed in the surgery section by the two sections jointly, viz., those on antiseptics.

OPERATIVE TREATMENT OF MALIGNANT RECTAL AFFECTIONS.

PROFESSOR ESMARCH, in his paper on this subject before the surgical section, laid down the same principles of treatment for cancer of the rectum as for cancer elsewhere. Removal of the disease must be early and entire. Cases were usually recognized too late, being earlier treated as piles, and a rectal examination too long deferred. The affection was painless in the early subject. Experience showed that after early and total removal a permanent cure resulted. The lymphatic glands were affected late and rarely. Czerny had cases of permanent recovery, although the disease had existed for three years. The prognosis was, therefore, good. First, as to principle, the amputation of the rectum above the limits of the disease was in every case indicated. The dangers were hemorrhage—which was to be controlled by care, double ligature of all vascular parts divided—and infection, which was to be guarded against by irrigation and drainage. To permit the fæces to pass, a large rubber drain was needed, surrounded by sublimated gauze. The peritoneum must inevitably be opened where amputation was high. Modern methods had reduced the mortality to twenty per cent., and the troubles resulting from the operation were insignificant. Suture of the two ends together was bad, causing gangrene and stricture. The anus and sphincter were to be left, and the coccyx need not be excised for space.

PROFESSOR VERNEUIL said he had done his first colotomy thirty years ago, and his first extirpation fifteen years ago. He at once found the removal of the disease was impossible, the patients objected or refused in many cases to allow the performance of colotomy. He then found the

incision of the cavernous stricture removed all complications and gave all the other advantages of colotomy. The whole length of the stricture must be split. The incision was made from the tip of the coccyx by a thermal cautery plunged in to meet the tip of the finger hooked above the stricture. Through this channel, by a canula, if necessary, an écraseur chain was passed, and the rest of the division completed. No blood was ever lost, and symptoms at once ceased. No deaths followed.

Professor Trélat denied the advantage claimed for the rectal extirpation, and pointed out the rapidity and malignity of the recurrence. He quoted one case, which he said was the type of many, where the removal of the cancer early, and when extremely small, was followed by a speedy and malignant recurrence. In one case he found, though the operation was normal and extra-peritoneal, that he had the small intestine in the artificial anus, and the patient died. He laid stress upon the color of the intestine, as the only part of recognition that did not deceive, being white or grayish white.

Mr. Sampson Gamgee, of Manchester, preferred the operation of inguinal colotomy, while admitting that the other operations had their indications, but that no one could dominate.

Mr. Marshall, of London, in support of the statements of Professor Verneuil, mentioned some cases where sinuses had been kept open in the peritoneum by tangle tents.

Professor Volkmann, of Halle, observed that colotomy, even in Mr. Bryant's hands, was a very dangerous operation, and that the statistics of extirpation were better than those of the colotomy of Bryant. Cancers, he said, varied in rapidity and malignity, according to their locality, and in the rectum they had little tendency to infiltrate early and recur soon. Even in desperate cases he had no return under long periods, in one case not for ten years. In chronic irritation a barrier surrounded the infiltrated carcinoma recti. The results of rectotomy had improved, and would go on doing so with improved *technique*. Asepsis and disinfection were normally powerful when the peritoneum was not opened; but when this was opened the dangers were great, and cleansing difficult. But dangerous as extirpation was, it was not so bad as colotomy, and recurrences were painless and not troublesome. The comfort of patients was also infinitely greater than it was after colotomy, discomfort being hardly felt save in diarrhœa. The selection of the cases, he went on to say, was also important, and he did not operate in any case where he could not reach the upper end of the disease by bimanual exploration under anæsthesia. The incision should be both forward and back to the coccyx, the anus alone being left, and no attempt should be made to unite the upper with the lower end, which should be stitched well down, and the cavities at the sides well drained. Extirpation he characterized as a blessed operation.

Mr. Henry Morris, of London, went over the English reasons for preferring colotomy in the lumbar region.

Professor Küster said that in extirpation he always stitched down when the peritoneum had been opened. He used iodoform in some cases, with temporary benefit. Cauterization was a proceeding from which good results were obtained in most of the cases where a permanent cure could not be expected. He would select either that or extirpation—very seldom colotomy.

Professor Pacquet, of Lille, read a paper on

UNILATERAL HYPEROSTOSIS OF ALL THE BONES OF THE HEAD,

excision of the upper jaw, and arrest of the hyperostosis in all the other bones; and he showed a preparation demonstrating the excision.

Professor Trélat, at the conclusion of the demonstration, observed that whatever might be said for the theory of the operation, the specimen shown to the section was one simply of osteo-myelitis.

Professor Pacquet thereupon made some amusement, withdrew the specimen as having been submitted by mistake, and showed another, which he declared to be the proper one.

Dr. A. Van Derveer, of Albany, read a paper on the

TREATMENT OF THE INTERMAXILLARY BONE IN CASES OF CLEFT PALATE

with double harelip.

Dr. Reginald Harrison, of Liverpool, read a paper on the

TREATMENT OF CERTAIN CASES OF PROSTATIC OBSTRUCTION BY SECTION OF THE GLAND.

Professor Volkmann said that drainage through the perineum, without incision of the prostate, was sufficient, and that the prostate afterward shrunk.

EXCISION AND ARTHROTOMY IN TUBERCULOUS JOINT DISEASES.

Professor Ollier, of Lyons, read a paper on the above subject, containing a general examination of the extent and results of resection and similar operations in tumor albus. Dealing with arthrotomy, he said there were no new operations. It was easy in superficial articulations and difficult in others. Drainage was often difficult, but could, however, be effected by canalization of the joints and foci of the affection. If undiscoverable they must be left. He laid great weight on the use of the cautery in the operation of arthrotomy. He admitted that resection beyond the epiphysial cartilages yielded deplorable results. Arthrotomy was better in young children. Amputation was no shield against the generalization of the tuberculous condition, for the infiltrated glands were left in every case.
